The earliest known route of vaccination was respiratory, by intranasal insufflation of powdered scab material containing variola virus from smallpox patients, reportedly practiced in China as early as the 10th century AD (see Chapters 1 and 32). The cutaneous route for such variolation involved breaking the skin with a sharp instrument, and it was used in India perhaps as early as in China, but it was not documented until the 16th century. Variolation was supplanted by safer cutaneous application of material from cowpox lesions, the method of “vaccination” known in the 18th century and first published by Edward Jenner.

After 15th-century experiments with hypodermic injection, the introduction of the needle and syringe [N-S] in the mid-19th century by Pravaz, Rynd, and Wood began a new era in medicine. Pasteur used a Pravaz syringe to inoculate sheep in the famed controlled challenge experiment demonstrating protection against anthrax, after which he honored Dr. Jenner by broadening his predecessor’s term—vaccination—to mean the administration of immunizing agents for various diseases, not just smallpox.

With acceptance of the germ theory and resulting sterilization of medical equipment by the early 20th century, and with mass production of needles and glass [later plastic] syringes by mid-century, hypodermic injection became the norm for convenient, accurate, and certain administration of most vaccines and many drugs. Regrettably, aseptic practice was ignored in many developing countries, and by nonmedical-intravenous-drug users everywhere, leading to widespread iatrogenic and self-inflicted disease transmission during that era once decried as just smallpox.

Other drawbacks of N-S include needlestick injuries to health care workers, needle-phobia and discomfort for patients facing increasingly crowded immunization schedules, and the costs and complexity of safe disposal of sharps in the medical waste stream. In the early 21st century, new targets for disease control and eradication, the expansion of philanthropic efforts to make expensive new vaccines affordable for the world’s children, and as reviewed by others. Reduced dosages of various vaccines into the skin, compared with full dosages into muscle or fat, have shown this tissue’s dosage-sparing ability, which is useful when vaccines are scarce, or unaffordable in full dosages. The skin is also the least invasive route, and thus, in theory, cutaneous delivery of new antigens is less likely to result in unanticipated serious adverse reactions—for example, intussusception after the first American oral rotavirus vaccine, Bell’s paralysis of the seventh cranial nerve after the first European intranasal influenza vaccine, and the occasional abscesses and nerve injury from needle injections into muscle and fat.

Of course, BCG and smallpox vaccines delivered into the skin are not always benign, and rarely they may result in uncontrolled replication and spread of the live antigen, causing serious complications, particularly in immunocompromised patients. Nevertheless, skin reactions in general are easier to detect early and access with palliatives or active therapeutic or anti-inflammatory agents than are reactions in deeper tissues.

Finally, successful delivery of antigen by cutaneous vaccination is relatively sure, although not as certain as the “gold standard” of needle injection. And, as with needles, lack of cooperation by some infants and children can be overcome with firm restraint. In contrast, oral doses can be spit out or vomited, and intranasal doses sneezed out or blocked by mucus or purulent rhinitis. Some pulmonary delivery methods require patient-initiated inhalation (see Figure 61-8E), or they may take from 30 seconds to over 2 minutes to administer by mask or prong (see Figure 61-7A,B,E,F). Such drawbacks may raise doubts about successful delivery of the antigen.

An unstandardized and inconsistent nomenclature to describe vaccination targeting the skin is found in the literature.
Alternative vaccine delivery methods

(eg, cutaneous, dermal, epicutaneous, epidermal, intracutaneous, intradermal, intraepidermal, intraepithelial, patch, percutaneous, skin, topical, transcutaneous, and transdermal). Often, prefixes of Latin (intra, per, trans) or Greek (epi) origin are paired hetero-lingually with root terms for skin of the other etymology, derma (G.) and cutis (L.). Some recent coinage results from commercial intent to claim trade names from among this synonymy. In this chapter, cutaneous vaccination is the preferred term to encompass all methods for delivery of antigen anywhere into or onto the skin. Classical intradermal injection, or just intradermal [ID], is generally reserved for a type of cutaneous vaccination in which a bolus of liquid is deposited into the dermis to raise a visible bleb, as in the traditional Mantoux injection [discussed below].

Anatomy and immunology of the skin

The outermost section of the skin is the epidermis, a stratified squamous epithelium that is usually about 0.1 mm thick but can be from 0.8 to 1.4 mm on the palms and soles [Figure 61-1A]. The stratum malpighii layer comprises the primary component of the epidermis, and its dividing and growing keratinocytes serve both a structural function—limiting the passage of water and other molecules—and an immunologic role. Keratinocytes germinate just above the basement membrane, which demarcates the boundary between epidermis and deeper dermis. These cells then grow, flatten, mature, and senesce in increasingly superficial strata until they reach the surface and are sloughed. The main product of this cell is keratinohyalin, a dense lipid that helps form a waterproof barrier. The lateral edges of adjacent keratinocytes are tightly linked by desmosomes, which maintain the strength of the epidermis and also contribute to its resistance to the passage of foreign matter or molecules.\(^5^1,\,5^2\)

The topmost horny layer of the epidermis is the stratum corneum, comprised of staggered courses of dead keratinocytes—also known as corneocytes—in a lipid bilayer matrix. This stack of 10 to 20 cells, 10 to 20 \(\mu\)m thick, is the principal obstacle to the introduction of vaccine antigen for cutaneous vaccination. Below the epidermis and basement membrane lies the dermis, about 1.5 to 3 mm thick, in which fibroblasts, fine collagen, elastic fibers, and most skin organelles, including small blood vessels, lymphatic vessels, nerves, hair follicles, and sweat and sebaceous glands, are found. The subcutaneous tissue below the skin, sometimes referred to as the hypodermis, consists primarily of fat; it varies widely in thickness between different body surfaces and, of course, individuals.

![Figure 61-1](image-url)
Skin thicknesses have been mapped in children to identify the histologic suitability of sites for cutaneous vaccination.\(^{34}\) Equally important is selecting skin sites that are easily accessed so as to minimize disrobing and loss of privacy. In smallpox eradication, the volar surface of the forearm was commonly used because it was quickly accessible, the vaccinator could hold the vaccine’s wrist for stabilization (and to prevent escape), and the scar was easily visible to verify prior vaccination.\(^{10,12,31}\)

The speed of diffusion of therapeutic substances transcellularly through the dead and living keratinocytes, and via the intercellular channels between them, correlates with smaller molecules (< 500 Da), lower melting points, increased lipophilicity [and correspondingly lower water solubility], higher [saturated] concentrations, and a relative lack of pendant groups that form hydrogen bonds that slow diffusion.\(^{32-34}\)

The specific mechanisms that produce the resulting immune response when vaccine antigen is introduced into the skin are not entirely clear. With stimulation, keratinocytes can produce proinflammatory cytokines [e.g., interleukin 1 [IL-1]] and can themselves function as antigen-presenting cells by displaying major histocompatibility complex [MHC] class II antigens [human leukocyte antigen [HLA]-DR], as well as intercellular adhesion molecules [ICAM-1].\(^{35}\) Epidermal Langerhans cells are believed to play a key role in cutaneous immunization, although dermal dendritic cells and other well-known immune system players, such as CD8+ and CD4+ T lymphocytes, mast cells, and macrophages, also circulate or reside in the epidermis or dermis.\(^{36,37,39,56–60}\)

The immature Langerhans cells reside like sentinels among the keratinocytes in the epidermis, comprising about a quarter of the skin surface area,\(^{41}\) where they efficiently capture foreign antigens by phagocytosis or endocytosis. Like dendritic cells in other tissues [see Chapter 5], on activation (see Figure 61-1A) these professional antigen-presenting cells [APC] process the antigen as they migrate to draining lymph nodes. There, new mature, they express high levels of class II MHC molecules, and present the antigen brought from the skin to T-helper [Th] lymphocytes, a critical step for the subsequent immune responses orchestrated by the latter cells.

**Delivery by sharp instruments or needles**

### Traditional vaccination for smallpox

During the more than 200 years of cutaneous vaccination against smallpox [see Chapter 32], a variety of sharp instruments have been used to cut, scratch, poke, and otherwise penetrate into the epidermis [and unnecessarily deeper into the dermis], for inoculation of cowpox or vaccinia virus [Figure 61-2A,B,C,D].\(^{1}\) In the 18th and 19th centuries, the scarification method involved scratching one or more lines into the skin with a needle, scalpel [lanceet], or knife and rubbing vaccine into the resulting lesion. A rotary lancet first described in the 1870s consisted of a shaft attached to the center of a small disk, the opposite [patient’s side] of which contained a central tine surrounded by smaller satellite tines. The twirling of the disk in a drop of vaccine on the skin produced much abrasion of the skin and often severe reactions from both vaccine and common bacterial contaminants. In the less traumatic multiple-pressure method introduced in the early 1900s, liquid vaccine was placed onto the skin and a straight surgical needle, held tangentially to the skin with its tip in the drop, was repeatedly and firmly pressed sideways into the limb 10 times for primary vaccination, and 30 times for revaccination.\(^{32}\) Multi-tine devices have also been used.\(^{33,34}\)

### Biliruncated needle

In the 1960s, Benjamin Rubin invented the bifurcated needle [see Figure 61-2D],\(^{35,36}\) for which Wyeth waived the royalties so that the World Health Organization (WHO) could produce it for smallpox eradication.\(^{37,38}\) The device holds approximately 2.5 µL by capillary action between its tines, which is applied perpendicularly into the skin. This uses one fifth of the typical dose volume needed by earlier multiple-pressure methods, but it requires a higher virus concentration. Its simplicity, portability, and economy greatly facilitated the latter half of smallpox eradication, particularly in Asia and East Africa.

### Tuberculosis vaccination

The bacille Calmette-Guérin vaccine for the prevention of disease from *Mycobacterium tuberculosis* was originally administered orally in the 1920s [see Chapter 35]. Safety concerns prompted a shift to cutaneous administration by ID needle injection [1927],\(^{49}\) and later multiple puncture [1939].\(^{50–52}\) scarification [1947], and multi-tine devices [Figure 61-2, images A, C, G, F].\(^{54–57,73}\) as described earlier for smallpox vaccine. BCG has also been delivered cutaneously by jet injectors\(^{54}\) and bifurcated needles.\(^{75}\)

### Mantoux method

The needle technique for *classical intradermal* injection, as used for BCG, was developed in the early 20th century by Felix Mendel\(^{76}\) and separately by Charles Mantoux\(^{77}\) for the administration of tuberculin [now replaced by purified protein derivative] used for diagnosis of tuberculosis infection. Now referred to as the Mantoux method, this procedure has become the common route for ID injection of various antigens [see Figure 61-2G]. A short-bevel, fine-gauge needle, usually 27 gauge (0.016 inch, 0.4060 mm diameter), is inserted, bevel up, at a 5 to 15-degree angle into slightly stretched skin, often the volar surface of the forearm.\(^{78}\) The tip is advanced about 3 mm until the entire bevel is covered. Upon injection of fluid, proper location of the bevel in the dermis creates a bleb, or a wheal, as the basement membrane and epidermis above are stretched by the fluid. Leakage into the skin indicates insufficient penetration to cover the bevel. Failure to produce a bleb indicates an improperly deep location of the fluid in the subcutaneous tissue. Drawbacks to the Mantoux method for mass vaccination campaigns are the training, skill, and extra time needed to accomplish it correctly.

### Reinventing the wheal

The potential dosage-sparing effect of ID vaccination, reducing the amount of antigen needed by up to 80% [by reducing the volume from 0.5 to 0.1 mL], has prompted renewed attention to this route because of concerns about emerging threats such as pandemic influenza, severe acute respiratory syndrome (SARS), and bioterrorism, which may leave populations vulnerable because of insufficient vaccine supply. Both old and new techniques can more easily achieve the *classical intradermal* injection of the Mantoux method, depositing the injectate into the skin to produce a raised bleb or wheal of temporary induration. Since the 1960s, multifeed-nozzle jet injectors (see “Jet injection”, later) have allowed ID delivery of smallpox, BCG, and other vaccines by using these specialized nozzles [see Figure 61-2E].\(^{52,79–81}\) Some adaptations of modern disposable syringe jet injector technology also achieve *classical intradermal* injection, namely the Tropis\(^{82}\) and the Bioject ID-Pen\(^{83}\) [see Figure 61-2F,K, and Table 61-1].

### Mini-needle

To circumvent the amount of skill and time needed for successful Mantoux injection, Becton, Dickinson [BD]\(^{84}\) developed a prefilled glass syringe with a staked, 30-gauge [outer diameter [OD], ~ 0.305 mm] mini-needle, which projects only 1.5 mm beyond its depth-limiting hub for intuitive perpendicular insertion into the skin [see Figure 61-2H].\(^{33,34}\) Termed the Soluvia Micro-Delivery System, it was licensed exclusively by Sanofi Pasteur\(^{85}\) for certain vaccine applications.
The Soluvia's first major clinical trial (although unidentified in the publication) was for the ID trial arm using an investigational GlaxoSmithKline (GSK) influenza vaccine. Later, Sanofi Pasteur undertook a series of clinical trials with its own trivalent, inactivated influenza vaccine, which led to marketing approval in Europe in 2009 for ID delivery of its Intanza and IDFlu products. These contained either 9 μg of viral hemagglutinin per strain per 0.1 mL for adults through age 59, or a full [non-dosage sparing] 15 μg for those 60 and older.

In the US trials cited in the product insert, Sanofi Pasteur's US-made Fluzone Intradermal product, containing 9μg per strain, was found to induce geometric mean titers (GMTs) of hemagglutination-inhibiting antibody that were non-inferior to those of control patients receiving conventional Fluzone by the IM route with 15 μg per strain. In 2011, the US Food and Drug Administration (FDA) licensed the vaccine and its unique prefilled delivery system, with an indication that it be used only for patients 18 to 64 years of age. Several other countries [eg,
Canada, Australia, New Zealand) have also licensed a Sanoﬁ influenza vaccine in the Soluva mini-needle delivery system. A pre-filled, empty, sterile version of the Soluva mini-needle syringe is potentially available to others for end-user ﬁlling. Detaching its hub exposes the full needle length to access conventional vials. Potential applications include post-exposure rabies prophylaxis in the developing world, for which a clinical trial demonstrated protective seroconversion comparable to a full dosage by the IM route28 (see “Other conventional vaccines”, later), as well as delivery of protein-based therapeutics, among others.  

A 34-gauge (OD, ~ 0.178 mm) version of the Soluva, without the bulky plastic emballage required to shield the needle for health workers, is sized for preclinical animal experiments. These out the bulky plastic emballage required to shield the needle for a clinical trial demonstrated protective seroconversion compared with larger dosages by the SC and IM routes.  

Paracoccidioidomycosis, plague, and staphylococcal pathogens or toxins.  

Adapter for Mantoux Injection  

A novel syringe adapter (see Figure 61-2I), designed for quicker insertion and improved consistency over the traditional Mantoux technique (see Figure 61-2G), guides the needle to its appropriate position in the skin to produce the desired bleb. In human trials conducted by PATH once known as the Program for Appropriate Technology in Health, the adapter’s Luer interface was ﬁtted to conventional 1.0-mL syringes, and injections of 0.1 mL produced desired blebs in 100% of 20-bevel-up and 20-bevel-down injections, yielding mean diameters of 9.3 mm, ±0.9 mm SD (range, 7 to 12 mm), with ID deposition conﬁrmed by ultrasound in all patients. The device was developed by SID Technologies, with ﬁnancial and technical support from the Centers for Disease Control and Prevention (CDC), West Pharmaceutical Services, and PATH, which has rights in the developing world for rabies vaccination and other applications. At licensure, West will manufacture and market the adapter in the United States and other developed countries.  

Other intradermal vaccines  

In addition to smallpox and BCG, and a combined BCG-and-smallpox vaccine, over a dozen other vaccine types have been administered intradermally.  

Inﬂuenza  

A substantial literature documents equivalent immunogenicity, occasional superiority, and, less commonly, lower responses to influenza vaccination by the ID route using needle-syringe compared with larger dosages by the SC and IM routes.  

Among published 21st-century ID inﬂuenza studies not included in the Young and Marra review was a study of children in Hong Kong given 2005–06 seasonal trivalent vaccine (Fluarix, GSK). It found 0.1 mL ID dosages to be comparably immunogenic with full 15-μg dosages given intramuscularly (seven of eight in the 18- to 60-year age range, four of six trials among those older than 60 years). ID superiority was found (without dosage sparing) in the remaining two studies in the older group. As usual, local reactions were consistently more frequent by the ID route. Among published 21st-century ID inﬂuenza studies not included in the Young and Marra review was a study of children in Hong Kong given 2005–06 seasonal trivalent vaccine (Fluarix, GSK). It found 0.1 mL ID dosages to be comparably immunogenic with full 15-μg dosages given intramuscularly (seven of eight in the 18- to 60-year age range, four of six trials among those older than 60 years). ID superiority was found (without dosage sparing) in the remaining two studies in the older group. As usual, local reactions were consistently more frequent by the ID route.  

Twenty-ﬁve years after the ﬁnal mid-20th-century ID inﬂuenza studies, two papers were published simultaneously in 2004, soon after several national shortages had revived interest in dosage sparing. Among 240 hits on literature searches through May 2011 for intradermal inﬂuenza vaccination studies published since 1950, Young and Marra called 205 that reported on nonseasonal vaccines (such as avian H5N1 or pandemic H1N1), or were duplicates or otherwise inappropriate. From the remaining 35, they excluded 22, which were either animal studies, were nonrandomized, used obsolete whole-virus antigen, or assessed immunity outside the selected window of 21 to 28 days after vaccination. They comprehensively compared the remaining 13 reports of split-virus studies, all from 2004 onward among adults 18 years of age and older.  

As in 20th-century reports, Young and Marra found dosages 40% to 80% smaller by the ID route in most studies to be comparably immunogenic with full 15-μg dosages given intramuscularly (seven of eight in the 18- to 60-year age range, four of six trials among those older than 60 years). ID superiority was found (without dosage sparing) in the remaining two studies in the older group. As usual, local reactions were consistently more frequent by the ID route. Among published 21st-century ID inﬂuenza studies not included in the Young and Marra review was a study of children in Hong Kong given 2005–06 seasonal trivalent vaccine (Fluarix, GSK). It found 0.1 mL ID dosages to be comparably immunogenic with full 0.5-mL IM ones, with increased but tolerable induration and erythema after ID delivery. Another study in Texas administered investigational, monovalent avian A/H5N1 antigen to adults in dosages of 3 and 5 μg by the ID route, and 15 and 45 μg by the IM route. All dosages less
than 45 μg by either route induced very poor responses, whereas 45 μg by the IM route induced a fourfold titer rise and titers of 40 or greater in 56% after two doses.

One multicenter study encompassed a range of four dosages of hemagglutinin per vaccine strain of the 2004–05 formulation of Fluzone, comparing 15 μg by IM needle, 9 and 6 μg intradermally by Soluvia mini-needle syringe, and 3 μg by Mantoux injection. ID by GMT, the 6- and 9-μg ID doses were non-inferior to the IM control for all three strains, but the 3-μg ID dose was non-inferior only for the A/H3N2/Wyoming strain. Other studies of the Fluzone ID vaccine delivered by Soluvia mini-needle were described above (see “Reinventing the wheel”, earlier).

When low-dose ID vaccine is compared only with full-dosage by the IM route, it cannot be ascertained whether a low dosage into the muscle (usually with fewer local reactions) would have performed as well. Belshe and colleagues addressed that question by adding a third arm to a trial of low-dose influenza vaccine by traditional Mantoux injection by the ID route, versus control. They found that low dosages by either the ID or the IM route were almost as immunogenic as the full-dosage IM control. 149

Poliovirus

In Salk’s first clinical trials with inactivated polio vaccine, it was administered by the ID route, 156,157 which was routinely used for millions of Danes in the mid 1950s, 158,159 and responses in studies were good up to the early 1990s. 160-164 As polio eradication nears its goal, it will be necessary to remove from circulation the live Sabin strains of oral polio vaccine (OPV), with their propensity to revert to virulence and to circulate from vaccinees to others, and to replace them with injectable, inactivated polio vaccine (IPV). However, the latter vaccine in full 0.5-mL dosages costs about 20 times as much per dose as OPV, promoting a search for cost-saving strategies that also avoid the introduction of needles into the polio eradication program. 165

Recent clinical research in Oman sponsored by WHO and others found seroconversion rates equivalent to full dosages given intramuscularly when IPV was delivered intradermally by needle-free jet injectors in 0.1 mL dosage-sparing volumes into the skin to infants at 2, 4, and 6 months of age, 166,167 but GMTs were consistently lower. At the earlier ages of 6, 10, and 14 weeks, studied in Cuba, the ID responses were somewhat lower, perhaps from maternal anti-body interference. 168 A study in the Philippines compared one-fifth dosages by Mantoux injection with full dosages by the IM route at 6, 10, and 14 weeks of age, finding inverse titers of 8 or greater to all three types in 99% to 100% of all participants, concluding that the reduced-dosage ID route was non-inferior to the IM route. 169

An Indian study of older children, 6 to 9 months of age, using a different investigational jet injector for ID delivery, deemed more than half of the injections “inadequate” because of a wheel diameter of less than 3 mm, or because more than a “small drop” of vaccine remained on the skin surface. 170 Overall, seroconversion rates and GMTs to all polio types were lower by reduced-dosage by the ID route than by full IM dosages, especially for such “inadequate” injections. Another study in the Netherlands of the same device is underway. More are planned. 171

Yellow fever

The ID route was used extensively for the live attenuated yellow fever French neurotropic vaccine, which was given by ID scarification in the 1940s and 1950s in Francophone Africa (see Chapter 38). 172 The 17D strain showed both good 173 and poor 174 immune responses when jet-injected by the ID route. A recent review discussed evidence for dosage-sparing equivalence in skin using one-fifth the usual dosage. 174

Other conventional vaccines

Inactivated vaccines with good immune responses after ID injection include typhoid 175 and rabies. 176-178 The latter has been used widely for dosage-sparing purposes in the developing world. 179,180

Generally good results have been reported for ID hepatitis B, 181-182 with exceptions when antigen mass was prepared by a 10 to 1 reduction instead of the more common 5 to 1 reduction for the ID route, 183 in infants, 194-196 and with recombinant vaccine. 197-199 A recent meta-analysis among five comparable, randomized clinical trials totaling 757 subjects (in 234 published studies) found a “slight” (1.4%) decrement in seroprotection rates for hepatitis B by the ID route compared with the IM route. 200 In contrast, another meta-analysis found hepatitis B by ID route somewhat more immunogenic than by IM route among dialysis patients. 201

For meningococcal disease, one 1972 paper on group A vaccine 202 and unpublished data posted at ClinicalTrials.gov for a 2002 to 2004 study of the modern, non-protein-conjugated A/C/W-135 combination [Menomune] 203 found good results. These two are the only reported studies of any polysaccharide vaccines (including Haemophilus influenza type b, and conventional or conjugated pneumococcal) by the cutaneous route.

Mixed results for the ID route have been reported for cholera 204 and hepatitis A vaccines. 205,206 Other nonliving antigens studied rarely by this route include diphtheria-tetanus-pertussis, 207,208 tetanus, 209,210 tetanus-diphtheria, 211 tetanus-typoid, 212,213 tick-borne encephalitis, 214,215 and Rift Valley fever. 216 Similarly mixed results were found for live measles vaccines by the ID route. 217-220

Investigational vaccines

In the mid to late 2000s, the ID route was pursued for a wide variety of investigational vaccines, including dengue, 221 human immunodeficiency virus (HIV), 222 malaria, 223 and tuberculosis. 224,225 The ID route—as well as the IM—had led to the serendipitous discovery in an influenza model 226 that viral genes encoded into bacterial DNA could express their protein antigens in vivo, a seminal event in the modern era of recombinant nucleic acid vaccinology. 227 Gene proto-antigens to prevent influenza, 228 HIV or acquired immunodeficiency syndrome [AIDS], 229,230 smallpox, 231 and many other diseases are being inserted into both naked DNA/RNA 232 and various vectors such as modified vaccinia Ankara virus, for delivery by the ID route. ID jet injection has been used for immunomodulators such as interferon. 233

Novel methods to deliver antigen into the skin

Various commercial patch delivery systems developed since 1981 have demonstrated the ability of certain therapeutic agents (eg, scopolamine, nitroglycerin, clonidine, estradiol, fentanyl, nicotine, testosterone) to diffuse passively into bare, untreated skin without the use of the active technologies or enhancers described in the following paragraphs. 244 However, such passive diffusion usually works only for small molecules with certain physical characteristics. Thus, there are but a few animal models of immunization onto bare, untreated skin. 245,246 Newer methods to facilitate antigen delivery to the epidermis involve painlessly stripping, abrading, scraping, piercing, vaporizing, shocking, vibrating, bombarding, and otherwise permeabilizing the barrier of the stratum corneum. Some methods combine several processes. These have been detailed in reviews by others. 27,29,31,33,34,36,43,49,60,245-248

Stripping and abrading

Tape and friction

A variety of simple tools have been used to remove the stratum corneum. Common cellophane adhesive tape may be applied to the skin and pulled away, carrying away dead keratinocytes with each repetition. Such tape-stripping has been shown to enhance cytotoxic-T-cell and cytokine immune responses on subsequent application of various antigens and adjuvants to
the skin in mice.\textsuperscript{249–250} Similarly, rubbing gauze, emery paper, electrocardiographic (ECG) pads, or pumice on the skin removes cells by their abrasive effects, and this has been found to enhance immune responses in humans.\textsuperscript{254} Application of cyanoacrylate glue followed by stripping the skin to apply antigen to the exposed hair follicles has been described,\textsuperscript{257} but its practicality has been questioned.\textsuperscript{27}

**Skin preparation system and transcutaneous immunization**

Among methods that strip the skin, perhaps the most advanced is one that combines this step with the use of a remarkably potent adjuvant, the heat-labile enterotoxin (LT) of *Escherichia coli* (see “Bacterial exotoxins”, later). This effort was originally championed by Gregory M. Glenn, first at the Walter Reed Army Institute of Research, then at Iomai Corporation, and later at Intercell.\textsuperscript{258}

The vaccinator or the patient holds against the skin a device, the Skin Preparation System, developed by Iomai (Figure 61-3A).\textsuperscript{214} With the push of a button and the pull of a tab, a controlled pressure is applied to a sandpaper strip, which gently abrades and removes about 2.5% of the stratum corneum.\textsuperscript{252,261} Then, a patch containing LT as antigen alone, or containing LT as an adjuvant for another antigen, is applied to the skin; the process is called transcutaneous immunization.\textsuperscript{252–263} LT alone is intended to induce immunity against enterotoxigenic *E. coli* (ETEC), the cause of traveler’s diarrhea, or against *Vibrio cholera*, with\textsuperscript{216} or without\textsuperscript{257,266} ETEC colonization factor.

An initial, randomized, blinded field trial among travelers to Guatemala and Mexico found 75% efficacy for the patch with LT alone in protecting from moderate to severe diarrhea.\textsuperscript{269} In 2010, Intercell reported mixed results from two follow-up field studies.\textsuperscript{267,271} In a pivotal phase 3 trial for travelers diarrhea

![Figure 61-3](image-url)
A clinical trial of the MEA measured transdermal water loss (TEWL) as a surrogate indicator for removal of the stratum corneum after each of five consecutive swipes across the same site on the volar forearm of volunteers. Projection heights of 100, 150, and 200 μm showed steadily increasing rates of TEWL, with the tallest projections producing the greatest water loss. Control swipes with fibrous and sandpaper ECG pads showed little or no TEWL. A human trial, however, in which rabbits vaccine was applied before or after four "rubs" of the device over four separate deltoid skin sites did not detect any immune response after three dosings on days 0, 7, and 21.

**Shaving and brushing**

The razor and the brush can also remove layers of the stratum corneum. In a clinical trial of adenovirus vectors encoded to express influenza hemagglutinin antigen, the abdominal skin of 24 adults was shaved with a disposable, twin-blade razor, followed by “gentle brushing with a soft-bristle toothbrush for 30 strokes” and application of the antigen with an occlusive Tegaderm patch. Two doses 28 days apart at the highest dosage level produced four-fold rises in HI titer with 67% of the cutaneous vaccines (there was no control group receiving conventional parenteral delivery of either the recombinant vaccine vector or a licensed inactivated influenza vaccine). Occasional mild erythema at the abdominal site was reported in 61% and rash or itching in 39% of patients.

This same research team, studying mice, substituted an electric trimmer for shaving but otherwise used similar brushing to demonstrate that topical application of nonreplicating E. coli vectors overproducing antigens for *Clostridium tetani* and *B. anthracis* were immunogenic. Control animals demonstrated that depilation alone had little effect, what made the difference was the mild brushing, which produced minimal irritation [Draize score, 1]. Others studying Japanese encephalitis vaccine in an animal model supplemented skin shaving with a commercial depilatory cream, followed by occlusion of the site with an impermeable covering. The practicality of such steps in routine immunization of humans is uncertain.

**Poking and piercing**

As with cutaneous vaccination in general, a diverse terminology is applied to microprojections for perforating the superficial skin to deliver the drug. Microtools, microneedles, microblades, micropoints, microtubes, and nanopatches have been used. This chapter uses microneedles for the broad category of all such projections shorter than 1,000 μm, reserving mini-needles for those of 1 mm or longer, whether solid or hollow (see “Mini-needles” and “Microrasps”, earlier). The following sections divide microneedles into functional subcategories.

**Uncoated microneedles**

Earlier, we described methods in which vaccine or drug is applied to the site after it is prepared. The 3M Corporation developed an uncoated microneedle device to prepare the skin by perforating it. Although not licensed (or even intended) for vaccine or drug, its 3M *Microchannel Skin System* of microneedles appeared on the US market in 2011 as a “pretreatment method for professional medical or cosmetic dermatologists to create microchannels in the skin” [see Figure 61-3B]. Each application creates 351 holes through the stratum corneum into the epidermis. Other investigational technologies of uncoated microneedles are the MicroCor, and the Functional MicroArray patch, and the Micro-Trans.
for variable periods of time in the epidermal layer while antigen or other drug elutes and diffuses. To date, only limited published data have demonstrated suitability for human vaccination, in contrast to therapeutic drugs.

One example of drug-coated microneedles that appears closest to marketing approval is the investigational Zosano Pharma ZIP Patch platform [formerly known as Macroflux] [see Figure 61-3C]. Its titanium projections vary from 225 to 600 μm in height and are packed into an area of 1 to 2 cm² at densities from 140 to 650 tines per square centimeter. They are inserted by a spring-mounted applicator and held in place by an adhesive patch. The most advanced applications for these microneedles are delivery of parathyroid hormone to treat osteoporosis, already studied clinically, and erythropoietin to treat anemia.

Regarding vaccine applications, a graph from a human study of Zosano Pharma’s ZIP Flu influenza vaccine patch, applied for 5 or 10 minutes onto the skin, trended toward increased titers and seroprotection compared with an IM control injection.296,297 (no further details were provided, nor could a public clinical trials registration be found).

A hairless guinea pig model was used to study ovalbumin on the patch’s microneedles as a representative, large antigenic protein.298,299 It was administered in two doses 4 weeks apart. It induced post-booster titers comparable to those of control IM, SC, and ID Mantoux-strength injections at higher dosages, and it surpassed IM and SC routes at lower dosages. Other preclinical studies of the system demonstrated delivery of oligonucleotides300 and the peptide hormone desmopressin.301 The company reports animal work with tetanus, diphtheria, Lyme disease, and hepatitis B (DNA) vaccine antigens.

Another coated-microneedle platform is the solid microstructured transdermal system (sMTS), from Zosano Pharma’s ZIP Patch platform. Its titanium projections vary from 225 to 600 μm in height and are packed into an area of 1 to 2 cm² at densities from 140 to 650 tines per square centimeter. They are inserted by a spring-mounted applicator and held in place by an adhesive patch. The most advanced applications for these microneedles are delivery of parathyroid hormone to treat osteoporosis, already studied clinically, and erythropoietin to treat anemia.

resist heat degradation and allow transport and storage outside the cold chain. A hydrogel polymer is proposed by Corium International as a binder-cum-adhesive for active pharmaceutical ingredients, and it will dissolve with delivery into the skin.

In Japan, CosMED markets a cosmetic MicroHyala microneedle array containing hyaluronate, which dissolves in 60 to 90 minutes, and vaccine applications are planned. Many others also pursue dissolvable microneedles.

**Hollow Microneedles**

Hollow microneedles are short enough, in theory, to be painless, as they are designed to inject therapeutic liquids through their tiny lumens. A hydrogel polymer is proposed by Corium International as a binder-cum-adhesive for active pharmaceutical ingredients, and it will dissolve with delivery into the skin.

for cutaneous delivery. It consists of three hollow 600-μm-tall microneedles of beveled pyramidal shape mounted on an adapter with laser interface for fitting onto a conventional syringe for liquid vaccine or drug (see Figure 61-4C). In 2010, it was cleared by the FDA for injection of any drug approved for ID delivery. It also holds a CE mark for marketing in Europe.

Adult volunteers vaccinated intradermally by a similar MicronJet version (four microneedles of 450 μm height each) received reduced 3 or 6-μg-particle single doses, or full 15-μg doses by IM route, of licensed alpha-RIX (Fluarix, GSK) 2007–08 seasonal influenza vaccine. By day 21, all three study arms developed comparable increases in GMTs and satisfied European criteria for relicensure of seasonal influenza vaccines in full. Local reactions were more frequent than by the IM route, but they were mild and transient. Similar dosage-sparing trials for 2009–10 monovalent H1N1 influenza vaccine and 2010–11 trivalent vaccine confirmed comparable or superior immune responses for the ID route versus IM. Another hollow microneedle system is 3M’s hollow micro-structured transdermal system (hMTS). Its patient-contact surface contains 18 microneedles of 500 to 900 μm in length, whose lumina of 10 to 40 μm in diameter deliver liquid volumes ranging from 0.3 to 1.5 mL (see Figure 61-4E). A spring-powered device contains liquid drug prefilled into a glass dose chamber. Upon triggering, the stopper of the chamber is pierced by a spike, through which the dose passes and is forced slowly over a period of 5 to 40 minutes through the microneedles into the skin of the upper arm or thigh. Adhesive on the patch keeps the system in place until delivery is complete. Delivery of equine tetanus antitoxin to swine as a model for delivery of monoclonal antibodies resulted in pharmacokinetic profiles of tetanus antitoxin similar to dosages via SC injection. Other groups have also pursued hollow microneedles.

Tattoo technology
Preclinical studies using commercial cosmetic tattoo machines delivered experimental DNA vaccine antigens on multineedle arrays (eg, nine), vibrating at frequencies of up to 100 Hz for durations of 5 to 20 seconds, resulting in thousands to tens of thousands of skin piercings per dose. Whether such a potentially painful delivery method would be practical, economical, or esthetically acceptable for human vaccination, as well as advantageous over other methods for cutaneous delivery, remains to be demonstrated.

Electromagnetic energy
The use of light or electricity, or the heat or radiation they produce, has been pursued to facilitate entry of drug into the skin, either during a brief or constant application of energy, or through the pathways created after a short pulse.

Laser light
Laser light has been used in various ways to breach the stratum corneum. In one technique, a brief pulse ablates this layer, after which drugs are applied directly onto the exposed epidermis, often with an occlusive patch, for the few hours until the stratum regenerates. The LAD (laser-assisted drug delivery) device generates an erbium-doped yttrium-aluminum garnet (YAG) laser beam whose energy is highly absorbed by skin. It was shown in adult volunteers to facilitate the anesthetic effect of the topical application of lidocaine, and it is licensed in the United States and Australia for that purpose.

A new system focuses the laser beam to create 150 pores per activation, with claimed pore diameters of 200 μm and selectable depths of 30, 60, or 90 μm, which should remain in the epidermis, not reaching dermal nerve endings. Another method uses a high-power pulsed laser to create a photomechanical wave that drives particles representing drug carriers through the stratum corneum. Clinical studies for intended vaccination using all such laser methods have not yet been reported.

Electrophoresis
Ioanophoresis—first demonstrated a century ago in rabbits—involve an electric current to drive charged molecules from an electrode of the same charge toward another of opposite charge located elsewhere on the body. Some licensed devices apply this technique for skin anesthesia. A related method is electro-osmosis, which induces a flow of solvent to carry uncharged molecules. Voltages greater than 1 volt in themselves increase skin permeability, perhaps by opening up pathways along hair follicles. But these techniques do not work well with larger molecules, which characterize many vaccine antigen proteins.

Thermoporation and electroporation
Thermoporation, also termed microporation, uses heat to vaporize tiny openings in the stratum corneum. In the PassPort system, this heat is generated by a disposable array of metallic filaments held momentarily against the skin by a device the size of a computer mouse (see Figure 61-4D). At activation, electric pulses are induced to heat the filaments. An adhesive patch containing vaccine or therapeutic agent is then applied over the micropores just created. In a hairless mouse model, this technique elicited 10 to 100-fold greater cellular and humoral responses to an adenoavirus vaccine than intact skin, as well as 100% protection to surrogate tumor challenge (27% for intact skin). In the same model, adeno-virus-vectorized melanoma antigen applied to the micropores roughly doubled the average onset time of tumors after challenge, and it protected one of six mice, compared with none of eight vaccinated controls with intact skin. Microporated recombinant influenza H5 hemagglutinin protected BALB/c mice from challenge with a lethal H5N1 strain. Skin micro pores also permitted the passage of insulin in pharmacokinetic human trials with historical controls, and in the other direction allowed interstitial fluid to be extracted for potential glucose monitoring.

Another device similarly generates micropores with heat induced by radiofrequency waves (ViaDerm). A different technique uses short, 100-μsec pulses of superheated steam in microliter amounts to remove the stratum corneum. Without apparent effect on deeper skin elements in a human cadaver model, this resulted in 1,000-fold in vitro increases in permeability to sulfonhomadine B and bovine serum albumin as surrogate molecules for drug or antigen.

Electroporation uses very short electrical pulses to produce in the intercellular lipid matrix of the stratum corneum temporary pores of nanometer-range diameters, which remain open and permeable for hours. In vitro and in vivo preclinical studies of this technique demonstrated skin entry of larger molecules, such as heparin (12 kDa), peptides, proteins (such as luteinizing-hormone-releasing hormone), and nucleic acids, with potentially extensive use for investigational DNA vaccines in animals and humans. The Easy Vax and related Derma Vax epidermal electroporation systems combine the application of antigen or drug-coated 2-mm-long mini-needles, followed by electroporation. Smallpox antigen in plasmid DNA was dried onto the tips of arrays and inserted into the skin of mice, and when followed by six electric pulses, it induced protection from smallpox challenge. A prostate cancer DNA vaccine was similarly administered. Electroporation by the IM route is also pursued to enhance vaccination with DNA antigens. A hollow needle injects the drug conventionally into muscle, while parallel solid needles surrounding the injected dose create the current to generate pores in the target muscle tissue. Investigational or marketed products are CythorLab, Easy Vax, Electrokinetic Device, ECM, MedPulse, and TriGrid among others.
Sound energy

To facilitate drug or antigen delivery, the connection between keratinocytes can be solubilized by ultrasonic waves and short-duration shock waves.\textsuperscript{384, 434-435} These are theorized to induce cavitation—the formation and collapse of microbubbles—which disrupts the intercellular bilayers in the stratum corneum. Low frequencies (<100 kHz) appear to work better than the higher frequencies used in therapeutic ultrasound (>1 MHz). Transdermal toxinoid immunization of mice was enhanced 10-fold compared with the SC route when subjected to ultrasound at 20 kHz.\textsuperscript{431} High-molecular-weight molecules delivered include insulin, crythrophoetin, interferon, and the epidermis at supersonic speeds.\textsuperscript{251} Various groups are pursuing ultrasound for enhanced drug delivery.\textsuperscript{384, 434-435}

Kinetic deposition

The transfection of cells by kinetic methods to deposit DNA-coated gold particles into them was pioneered in the 1980s.\textsuperscript{436} The Helios or PDS 1000/HE gene guns\textsuperscript{437} and the Accell injector\textsuperscript{437} have become standard bench tools for biolistic delivery of nucleic acid plasmids into a wide variety of plants and animals to transfet them to express the encoded genes.\textsuperscript{385, 387, 438} Delivery of DNA into the skin overcomes the usual polarized T-helper cell type 1 [Th1] response when DNA is delivered into muscle.\textsuperscript{30, 439, 440} These devices are unavailable for human vaccination (patent rights are held by PowderMed\textsuperscript{441}). Documenting the safety of DNA as an antigen by any route remains a major regulatory obstacle for such a paradigm shift in human vaccination.\textsuperscript{30}

Powder or particle technology

The proprietary terms epidermal powder immunization [EPI] and particle-mediated epidermal delivery [PMED] refer to the use of helium gas to blow powdered proteins, polynucleotides, or inactivated pathogens [EPI] or DNA-coated particles [PMED] into the skin at supersonic speeds.\textsuperscript{384} This unique method of vaccination was developed in the early 1990s by Oxford BioSciences, which over the years was renamed Powderject, acquired by Chiron,\textsuperscript{442} spun off as PowderMed,\textsuperscript{443} and finally acquired by Pfizer\textsuperscript{444} in 2006. Delivery is by either reusable (XR series) or single-use disposable (ND series) devices (see figure 61-4E), with the latter targeted for commercialization.

Conventional protein antigens for delivery by EPI are spray-dried into powders of suitable density and size (20 to 70 μm).\textsuperscript{445, 446} but the economics of manufacturing such formulations may be an obstacle.\textsuperscript{40} For DNA vaccines delivered by PMED, plasmids coding for desired antigens are coated onto gold beads (1 to 3 μm in diameter) and, when deposited into epidermal antigen-presenting cells, they are cluted and transcribed.\textsuperscript{447} A number of preclinical studies in various animal models have been conducted.\textsuperscript{442, 445, 448, 449}

Human trials of DNA vaccines containing up to one order of magnitude less antigen than the amount used for IM routes have induced humoral and cellular immune responses for hepatitis B in subjects both naïve and previously vaccinated with conventional vaccine.\textsuperscript{410-413} PMED vaccination has also been studied for DNA priming in trials of malaria vaccine,\textsuperscript{414, 415} has produced seroprotective immune responses by DNA vaccine for seasonal strains of influenza,\textsuperscript{83, 416} and has reduced influenza symptoms and viral shedding after human challenge.\textsuperscript{457} Clinical trials still ongoing or unpublished are studying antigens for H5 avian influenza (DNA),\textsuperscript{416} herpes simplex virus 2,\textsuperscript{459} HIV and non–small cell lung cancer.\textsuperscript{460, 461}

In the hepatitis B and influenza trials cited earlier, there were no severe local reactions, but erythema, swelling, and flaking or crust formation occurred in nearly all subjects, albeit resolving by day 28. Skin discoloration, however, persisted through day 56 in 29 (97%) of 30 subjects,\textsuperscript{442} through day 180 in 21 (25%) of 84 injection sites,\textsuperscript{442} and beyond 12 months in 5 (25%) of 20 patients with long-term follow-up.\textsuperscript{452} No anti-double-stranded DNA antibodies were detected. The deposition of the gold particles was studied in pigs, in which most were deposited in the stratum corneum and epidermis and were eventually sloughed by exfoliation by 28 days.\textsuperscript{463} At days 56 and 141 after administration, a few particles remained in the basal epidermal layer and in macrophages in the dermis and regional lymph nodes. Six clinical trials of PMED were initiated in 2006 and reported complete by 2007 or 2008 for delivery of investigational herpes simplex type 2 vaccine; seasonal, pandemic, and trivalent DNA influenza vaccines; and hepatitis B vaccine.\textsuperscript{465} Results were not yet published as of January 2012. Preclinical studies of EPI or PMED in murine, porcine, and primate models have shown immunogenicity or protection for either powdered or DNA plasmid antigens for various other pathogens, including Eurasian encephalitis viruses,\textsuperscript{466} hantaviruses,\textsuperscript{467} HIV,\textsuperscript{468} influenza H5N1,\textsuperscript{468} malaria,\textsuperscript{469} SARS coronavirus,\textsuperscript{470} smallpox,\textsuperscript{470} and Venezuelan equine encephalitis.\textsuperscript{471}

Other kinetic and thermal methods

Another delivery method, termed needle-free solid dose injector (SDI), is from a British firm, Glide Pharma (see figure 61-4G).\textsuperscript{472-475} It uses a spring-loaded device to quickly push into SC tissue a sharp, pointed, biodegradable “pioneer tip” and the solid or semisolid medication behind it in the chamber—both about the width of a grain of rice. Microscission involves a stream of gas containing tiny crystals of inert aluminum oxide to bombard small areas of the skin. A mask on the skin limits the sandblasting effect to narrow areas, so channels are created in the stratum corneum to which drug is then applied.\textsuperscript{476} Another method uses a fast and powerful contractile fiber-activated pump to fire drug at the skin with sufficient velocity to penetrate the epidermis.\textsuperscript{477} A miniaturized form of traditional jet injection uses piezoelectric transducers to propel liquid microjets into the skin.\textsuperscript{478}

Adjuvants and enhancers for cutaneous vaccination

As bathers notice in their fingertips, prolonged wetting of the skin, or occluding it to hold in body moisture, produces fluid accumulation in intercellular spaces and swelling of the keratinocytes, which permits enhanced passage of applied agents.\textsuperscript{477} Rubbing the skin with acetone also enhances antigen passage by extracting epidermal lipids.\textsuperscript{479}

Bacterial exotoxins

Discovery of the remarkable adjuvant effect of bacterial ADP-ribosylating exotoxins, such as the B [binding] subunits of cholera toxin and the structurally similar, heat-labile toxin of enterotoxigenic E. coli, has prompted much interest in using these to enhance cutaneous delivery.\textsuperscript{39, 134, 477-481} The group that has progressed the furthest in clinical trials is Intercell,\textsuperscript{218} the successor to pioneering work begun by the US Army and then by Iomai (see “Skin preparation system and transcutaneous immunisation”, earlier). Another group used cholera toxin as an adjuvant when administering influenza vaccine to mice with skin pretreated with microneedles.\textsuperscript{482}

For safety reasons, these toxins have been engineered, or mutants selected, to reduce toxicity while retaining adjuvanticity.\textsuperscript{483, 484-488} Nevertheless, one such use as adjuvant in a licensed, Swiss-made intranasal influenza vaccine was hypothesized as the cause of temporary paralysis of the seventh cranial nerve (Bell’s palsy), prompting market withdrawal.\textsuperscript{485}

Chemical, protein and colloidal enhancers

Chemical penetration enhancers under consideration as skin adjuvants, alone or in conjunction with iontophoresis, ultrasound, or electroporation methods, include oleic and retinoic acids,\textsuperscript{486} dimethylsulfoxide (DMSO), ethanol, limonene, polysorbate, and others.\textsuperscript{487} Flagellin, a bacterial surface component
protein, was engineered to express influenza nucleoprotein epitope and applied to the bare skin of mice, inducing virus-specific interferon-γ T cells.34 Certain colloids may serve as antigen carriers.35 Deformable lipid vesicles ("transfersomes") containing tetanus toxoid applied to animal skin yielded comparable immune responses with alum-adjuncted tetanus toxoid given by the IM route.495

**Combination methods**

Other novel methods of delivery include the use of short needles to poke an initial opening into the skin, followed immediately by SC or IM jet injection with much lower pressures than otherwise would be needed.490,491

### Jet injection

#### History and applications

Jet injectors [JIs] squirt liquid under high pressure to deliver medication without needles into targeted tissues [Table 61-1].22,492-521 The technology was invented in France in the 1860s (Figure 61-5A)492,522-523 a patent was filed for in 1936,524 and it was reintroduced in the 1940s as the Hyprospray526 for patient self-injection with insulin [see Figure 61-5B]. In the 1950s, the US military developed a high-speed system [see Figure 61-5C], which was imitated by others [see Figure 61-5D,E,F,G,I], and the units were once referred to as jet guns for mass vaccination programs.528-532 Over the past half-century, JIs have been used to administer hundreds of millions, if not billions, of vaccine doses for mass campaigns in humans against smallpox,491-531 measles,532,533 mumps,491-541 mumps,491-541, polio,501,502 meningitis,543-545 influenza,546,547 yellow fever,533,538,548 cholera550 and other diseases.25,342,543,551-554 During the swine influenza mass campaign of 1976–77 in the United States, a substantial proportion of the approximately 43 million doses administered that season555 were by JIs (CDC, unpublished data).555,556

JIs have also been used for a wide variety of therapeutic drugs, including local328,557 and pre-general359,560 anesthetics,361 antibiotics,354,558 anticoagulants,362,363 antivirals,364,558 corticosteroids,365,565 antihypertensives,366,558 insulin526,572,573 and other hormones,574-576 and vitamins.367 Veterinary models for agricultural use are widespread.578 In recent years, the devices have been used to administer various antigens to both humans and animal models for a variety of investigational vaccines, including dengue,579-581,583-584,586 Japanese encephalitis,587 malaria,232 and melanoma.386

#### Occupational and patient safety, economics

Increasing concern for needle-stick injuries and possible transmission of bloodborne pathogens to health workers, as well as the more expensive needle-shielding syringes that occupational health regulations now require to reduce the risk of injury,587 have boosted interest in JIs in developed countries.588 Another economic factor is the high cost of proper disposal of highly regulated sharps waste, which is not required for used JI syringes [see “Disposable-syringe jet injectors”, later]. As the latter may be soiled with blood or tissue fluid, they should be discarded with conventional red-bag medical waste, along with used bandages and similar materials.589

For many developing countries, where inadvertent or intentional reuse of nonsterile needle-syringes is a serious problem,10,31 modeling indicated significant cost savings for the use of needle-free JIs compared with needle-syringes, especially when the indirect costs of iatrogenic disease resulting from the latter were included.490,598 [Current best practice aims for all vaccination syringes in these countries to be auto-disabling to prevent reuse,599 but this goal is far from achieved.]

#### Mechanical and clinical aspects

**Designs, power supplies, types**

Common features of all JIs include a dose chamber of sufficient strength to hold the liquid when pressurized, a moving piston at the proximal end to compress the liquid, and a tiny orifice (commonly ~ 0.12 mm in diameter, ranging from 0.05 to 0.36 mm493,593 at the distal end to focus the exiting stream for delivery into the patient. The pistons of the majority of modern JIs are pushed by the sudden release of energy stored in a compressed metal spring, and a few use compressed gas such as CO₂ or N₂ [see Table 61-1]. Investigational JIs are powered by the expanding pressure of chemical combustion, a technology similar to that found in automotive safety airbags,542,545,594,595 as well as by Lorentz-force electromagnetic induction.596

The source of energy to compress the spring is usually supplied manually or pedally through an integral or separate tool to apply mechanical advantage or hydraulic pressure. A few use electrical power from batteries or wall (main) electrical current. An experimental JI system controlled by electronic microprocessors has been proposed,596 but its cost and practicality for routine immunization remain unknown.

Although devices vary, peak pressures in the dose chambers range from 14 to 35 megapascals (~ 2,000 to 5,000 psi) and occur quite early so that the stream can puncture the skin. After the peak, pressures drop about one third to two thirds during a descending plateau phase until rapid tail-off at the end of the piston's stroke. The velocity of the jet stream exceeds 100 m/sec.597 Complete injection lasts about ½ to ¼ a second, depending on the volume delivered, the orifice cross-section, and other variables.

JIs can be classified in many ways: by their energy storage and sources, by intended market [human versus veterinary], by intended usage [eg, repeated self-administration of insulin by the same patient versus vaccination of consecutive patients], by how the dose chamber is filled [medication vial attached "on tool" versus filled "off tool"], by reusability of the entire device [single-use disposable versus reusable], and by reusability of the fluid pathway and patient-contact components [multisure versus disposable]. This last criterion results in a key distinction between multisure-nozzle jet injectors (MUNJIs) and disposable-syringe jet injectors (DSJIs, once called disposable-cartridge jet injectors), with major implications for immunization safety (see "Safety of multisure-nozzle jet injectors" and "Disposable-syringe jet injectors", later).

**Deposition in target tissues**

In vivo imaging indicates that jet-injected medication tends to spread along paths of least resistance in a generally conical distribution.598-604 The depth achieved depends primarily on the power imparted to the liquid, and on variables such as orifice diameter, viscosity of the dose, tautness and thickness of the skin and fat layer, and angle of injection.493,496,589,597,599,605,606 Only the SC compartment is reached by many DSJIs designed for self-administration by patients of insulin, hormones, and other drugs, as well as some MUNJIs used in dental anesthetics [eg, Fig. 61-5H].607,608

Most MUNJIs developed for mass vaccination campaigns are powered to reach IM tissues—for example, the Ped-O-Jet609 [see Figure 61-5C] and Med-E-Jet610 [see Figure 61-5E], as well as several new-generation DSJIs. The Biojector 2000 varies the orifice of different cartridges on the same injector to deliver either by the IM or the SC route [Figure 61-61].611,612 The PharmaJet613 (not shown) varies spring strength to apply mechanical advantage or hydraulic pressure. A few use electrical power from batteries or wall (main) electrical current. An experimental JI system controlled by electronic microprocessors has been proposed,596 but its cost and practicality for routine immunization remain unknown.

**Market/primary uses**: An, anesthetic; Av, antiviral; De, dentistry; Gh, growth hormone; Ho, hormone; Hu, human medicine; In, insulin; Mu, multiple; St, steroids; Un, unspecified; Va, vaccine; Ve, veterinary.

**Energy source/storage**: Ba, battery; Ch, chemical (via expanding gases of reaction or combustion); El, wall (mains) electricity; Ga, compressed gas (cylinder or electrical compressor); Hy, hydraulic fluid pressurized in foot-pump accumulator; Ma, manual muscle; Pe, pedal muscle; Sp, metal spring.

**Type**: DSJI, disposable-syringe jet injector; MUNJI, multiuse-nozzle jet injector; SUDJI, single-use disposable jet injector (entire unit discarded after use).

**Filling**: Md, multiple doses possible from dose chamber before refilling required; MF, manufacturer prefilled only; Off, off tool (dose chamber [syringe] is filled from vial before insertion into injector); On-F, on tool (primary container [vial] attaches temporarily to injector to fill dose chamber during filling but is removed before injection); On-I, on tool (primary container [vial] remains attached to injector to fill dose chambers repeatedly but stays attached during injections); Sd, dose chamber is a prefilled, standard drug cartridge (primary container).

**Target tissue**: ID, intradermal; IM, intramuscular; SC, subcutaneous.

*Approximate year(s) first introduced to market; or if not, year(s) investigational development initiated; or if not, year patent filed.

Device withdrawn from market, no longer manufactured, or abandoned in development.

Vision injector versions are licensed to Ferring Pharmaceuticals BV (ZomaJet), SciGen Ltd (SciTojet), JCR Pharmaceuticals (Twins-Jector EZ II), and Teva (Tjet for TEV-TROPIN human growth hormone).

Investigational device, or not yet sold commercially for routine use in humans or animals.

The cool click and Serุดet devices are the Vitajet 3 design licensed by Bioject to EMD Serono for delivery of the Saizen and Serostim brands of somatropin (recombinant human growth hormone) for treatment of growth hormone deficiency and AIDS wasting diseases, respectively.

The mhi-500 (by The Medical House, acquired by Bespak) device contains Vitajet 3 technology licensed by Bioject.

**Canine Transdermal Device** is an adaptation of the Bioject Vitajet3 jet injector licensed to Merial (Sanofi group) for delivery of its Oncept DNA vaccine for treatment of oral melanoma in dogs, licensed in the United States in 2010.

The Vetjet (by Merial) device is the Vitajet 3 design licensed by Bioject to Merial for delivery to cats of PureVax brand of feline leukemia virus vaccine.

The ZipTip (by Pfizer) is the INJEX design licensed to Pfizer for delivery of Genotropin recombinant human growth hormone.

Zogenix SUMAVEL DosePro delivers sumatriptan indicated for acute migraine and cluster headache. Novel borosilicate glass dose chamber prefilled by drug manufacturer.
great patient variation, it is no surprise that imaging data sug-
ggest that JIs often miss the intended IM or SC compartment.81,246 However, this may have little clinical relevance and may be no
different from needle injections, for which fat-pad thickness is
often underestimated when selecting needle length, or when the
needle is not fully inserted.1,81,343 In Russia, an unconventional
injection technique—intrapulmonary jet injection—gained
interest as first known jet injector. (From Béclard F. Présentation de l'injecteur de Galante, Séance du 18 Décembre, 1866, Prés. Bouchardat. Bulletin de l'Académie Impériale de Médecine (France) 32:321-327, 1866.)

Cutaneous delivery

As mentioned (see “Cutaneous vaccination”, earlier), there has
been a resurgence of interest in skin vaccination because of
its potential dosage-sparing capability and minimal invasive-
ness. Jet injectors for classic ID delivery offer the additional
advantage of simplicity over the tedious and difficult classic
Mantoux injection, as well as the ability to use existing off-the-
shelf vaccines without reformulation. Older MUNJI models,
such as the Ped-O-Jet, used specialized nozzles with recessed
orifices offset by 45 degrees from perpendicular to the skin, cre-
ating an air gap that weakened its jet stream so as to leave the
dose in the skin (see Figure 61-2E).

The Ped-O-Jet and to a much lesser extent other MUNJIs
[see Figure 61-5D] administered tens of millions of smallpox
vaccine doses for the first half of the WHO Smallpox Eradica-
tion Programme in South America and West Africa in the late 1960s
to early 1970s, until invention of the simpler and swifter bifur-
cated needle.1,51,536 JIs also delivered yellow fever1217 and
BCG vaccines614-628 by the ID route, as well as various tubercu-
losis skin testing (TST) antigens.624-632 However, variations in

Figure 61-5 Selected Multiuse Nozzle Jet Injectors (MUNJIs). (A) Aqua-puncture device of Galante et Compagnie,1 circa 1866, of historical
target tissue—the lung—was reached by “intrapulmonary” jet
injections (between the ribs) of antibiotics, bronchodilators, and
steroids. Manual hand crank to cock metal spring. Once used in routine immunization in medical clinics, and in mass campaigns. (Figure 61-5A, 523; 61-5B, 526; 61-5C, C inset, E, courtesy of James Gathany, Greg Knobloch [CDC Photographic Services]; 61-5D, courtesy of Public Health Image Library, CDC; 5F, courtesy of Medical International Technology;10:185-199, 1950.)

(G) ImoJet spring-powered MUNJI (Courtesy of Sanofi Pasteur) with remote power source (not shown), once used in
mass campaigns. (H) MadaJet (Mada International), a MUNJI still used for injections in dentistry, podiatry, and perhaps other medical specialties (no known use for vaccination). The teflon sheath over the nozzle is designed to deliver the anesthetic in a spray pattern that penetrates 2-3 mm
below the epithelium, producing a wheal that is 3-5 mm in diameter. (I) Hypospray professional model MUNJI (Robert P. Scherer Company) uses
manual hand crank to cock metal spring. Once used in routine immunization in medical clinics, and in mass campaigns. (Figure 61-5A, 523; 61-5B, 526; 61-5C, C inset, E, courtesy of James Gathany, Greg Knobloch [CDC Photographic Services]; 61-5D, courtesy of Public Health Image Library, CDC; 5F, courtesy of Medical International Technology;10:185-199, 1950.)

Alternative vaccine delivery methods
• Vaccines in development and new vaccine strategies

As described earlier (see “Poliomyelitis”), WHO and others involved in polio eradication are pursuing the use of DSJIs for needle-free, dosage-sparing ID delivery of IPV once OPV is discontinued for both technical reasons and cost [full-dosage

Figure 61-6 Selected Disposable-Syringe Jet Injectors (DSJIs), Licensed or Investigational (as noted). (A) Investigational LectraJet HS (high-speed) motorized DSJI (D’Antonio Consultants International®) features built-in motor and rechargeable battery for rapidly compressing metal spring between injections at rates exceeding 600 per hour, with battery capacity of >3,000 injections per charge. Capable of rapid, fingers-free loading and unloading of single-use syringes from (A, inset) a sterile-packaged, 30-unit magazine for mass vaccination. Magazine may also be mounted on nondominant forearm for vaccinator mobility. Capable of backup manual spring-cocking if batteries are depleted. (B) LectraJet M3 (manual) model DSJI, sharing the same common syringe as the adjacent HS model for rapid, fingers-free loading and unloading of syringes. IM or SC delivery set by varying syringe orifice diameter. Cocked using off-tool carrying case (not shown). Cleared for US marketing by FDA in 2009. Syringes and needle-free vial adaptors also supplied in individually wrapped sterile envelopes for routine immunization (not shown).

(C) Pharmajet Stratis® DSJI, for 0.5-mL dose delivery. Delivery IM or SC set by vaccinator technique (flat layer pinched up for SC). Cocked using off-tool carrying case (not shown). (C, inset) Syringe is filled by pulling back and breaking off its blue shaft and thumb tab from conventional single-dose and multidose vials using needle-free vial adaptor (not shown). On insertion into device, any excess liquid is returned to vial to minimize wastage of overfill. Cleared for US marketing by the FDA in 2011. See Figure 61-2J for intradermal DSJI from same device manufacturer. (D) Medijector Vision DSJI (Zogenix®), licensed as drug-device combination product for subcutaneous delivery of prefilled sumatriptan for treatment of migraine and headache. Uses novel, borosilicate-glass dose chamber prefilled by drug manufacturer. (G) Imule manufacturer-prefilled DSJI syringe® for Varicella vaccine (Institut Mérieux/Pasteur Mérieux Sérum & Vaccins®). The syringe served as both primary vaccine packaging in a presentation smaller than conventional single-dose glass vial (millimeter scale on left), as well as the single-use disposable syringe for jet injection. Upon removing the label (H, center), inserting into the Mini-Imojet DSJI (not shown), and removing the rubber cap (H, right), the dose was ready for injection. Studied in human trials for five vaccines® and found successful in immune responses and safety. Subsequently abandoned by the manufacturer. (I) Biojector 2000 DSJI (Bioject Medical Technologies®), capable of subcutaneous and intramuscular injections using syringes of differing orifice diameters. Cleared for US marketing by FDA in 1990s. Powered by compressed CO₂ cartridge, or by connection to separate compressed gas source. An investigational spacer for intradermal delivery (illustrated elsewhere) creates a 2-cm air gap to weaken the jet stream, leaving the injectate in the skin. Used by US Navy and Coast Guard for approximately one-third million vaccinations per year of sailors and dependents from 1997 through 2011. (J) ZetaJet metal-spring-powered DSJI,® features built-in crank for manual re-cocking of metal spring (Bioject Medical Technologies®). Uses different auto-disabling cartridges for SC, IM, and ID injections (licensed by US FDA in 2009). See Figure 61-2K for intradermal DSJI from same device manufacturer. (K) Investigational Iject DSJI,® designed for either single-use or reuse upon refitting with its manufacturer-prefilled borosilicate glass dose chamber. (Figure 61-6A, inset B, courtesy of D’Antonio Consultants International, Inc.; C, inset, courtesy of Pharmateut, Inc.; D, 6D, courtesy of Antares Pharma®; 6E, courtesy of Zogenix®; 6F, courtesy of National Medical Products®; 6G, courtesy of INJEX/Equidyne Systems®; 6H, courtesy of Bruce G. Weniger; 6I, courtesy of James Gathany (CDC Photographic Services); 6J, K, courtesy of Bioject Medical Technologies.)

This ID technique was pursued investigationally for local anesthesia® and DNA vaccines.®

For devices without a specialized ID nozzle, some vaccinators attach spacers or tubing to a regular nozzle, creating a gap between orifice and skin, which weakens the jet and provides space for a bleb that leaves the dose in the skin.®

Consequent TST reaction sizes® led WHO to discourage JI use for BCG and TST.®

This technique was pursued investigatively for local anesthetic® and DNA vaccines.®
IPV is 20 times more costly than OPV166,169,441. Other vaccines that have been studied for ID delivery by DSJIs include HIV/AIDS164,169, influenza162, and studies are underway or planned for dengue,258,357,540 human papillomavirus, and rabies. The PharmJet Tropis [see Figure 61-2J] and the Bioject ID Pen [see Figure 61-2K] are two new spring-powered DSJIs designed solely for ID delivery of 0.05 and 0.1 mL volumes. The former was licensed in the United States in 2011, and clearance for the latter is expected in 2012.

**Immune response**

A large body of clinical literature shows the immunogenicity of JIs to be usually equal to, and sometimes better than, that induced by conventional needle and syringe for a wide variety of vaccines.495,499,494 Among inactivated and toxoid vaccines, this includes anthrax,443-446 cholera,455 whole-cell diphtheria-tetanus-pertussis,455,500,541 diphtheria-tetanus,211 hepatitis A,440-451 hepatitis B,194,452-456 influenza,383,384,541 meningococcus,369,444 polio,459 tetanus,554,644,650,661 and typhoid448,462. With the exception of the variable delayed-hypersensitivity responses to BCG discussed earlier, other live vaccines inducing suitable immune responses when administered by JI into their usual tissue compartment are measles,256,259,305,358-360,456,653,660,664 measles-mumps-rubella,156 measles-smallpox,211 rubella,358,354 measles-smallpox-yellow fever,354,353,358,354,355,356,454,664 BCG-yellow fever,172,175-177,354,358,549

The immunogenicity or efficacy of traditional meningococcal polysaccharide vaccines administered by JIs have been demonstrated for serogroup A in the clinic211,445 and in outbreaks in the meningitis belt of western sub-Saharan Africa.411,470,474 as well as for serogroup C in South America211,445 and Africa.413,470 Jet injection of the neat capsular polysaccharide typhoid vaccine resulted in 87% seroconversion, versus 69% by needle-syringe [P < .05].454 Clinical studies have not yet been published of JI for modern protein-conjugated polysaccharide vaccines for H. influenzae type b, pneumococcus, or meningococcus.

A wide variety of investigational recombinant nucleic acid vaccines are being delivered in preclinical and clinical trials using various JIs.555,604,678-686

**Reactogenicity**

When JIs and needles used to deliver IM and SC injections are compared in terms of immediate pain, the results depend on the medication involved. Insulin, other nonirritating drugs, and nonadjuvanted vaccines are usually reported to result in either reduced or equivalent pain compared with needles.593,595,593,593,360,354,354,354,354,354 and to market with-ies added more evidence that MUNJIs could transmit pathogens between patients. This led to warnings and discontinuation of their use by public health authorities,718,719 and to market withdrawal of the Ped-O-Jet and discontinuation of its US military use in 1997.720,721

In the mid 2000s, a MUNJI was reengineered with disposable caps to try to prevent contaminating blood or tissue fluid from splashing back onto the reusable nozzle, potentially to infect the next patient.721 The cap contained three plastic washers with axially aligned central holes of about 1 mm in diameter for the jet stream to pass in one direction along the centimeter-wide gap between orifice and skin. However, after injections with saline of volunteers in China who carried hepatitis B virus, 8% of subsequent ejaculates into vials—representing the next vaccinees in a clinic or mass campaign—were found by polymerase chain reaction assay to contain hepatitis B antigen.722 High-speed microcinematography also revealed extensive splashback from the skin during injection with MUNJIs.723 This body of evidence supports the conclusion that the design of MUNJIs is inherently unsafe, and any reuse of fluid pathways or unsterile components that are in direct or indirect contact with consecutive patients should be abandoned. Even if contamination could be shown to be extremely rare, it is unlikely that policymakers could be convinced to set any level of acceptable risk.

Despite the recommendations against MUNJI use for vaccination by public health authorities,723,724 and their withdrawal by the US military,725 models such as the MadAJet166 (see Figure 61-5H) and SynJet166 continue to be used in the United States in dentistry and podiatry and perhaps other specialties. Also, despite the Chinese venue for the definitive study documenting MUNJI cross-contamination, the Chinese Food and Drug Administration was reported in February of 2011 to...
Disposable-syringe jet injectors (DSJIs)

To overcome concerns over MUNJIs and their withdrawal, a new generation of safer, disposable-syringe JIs have appeared since the early 1990s (see Table 61-1). Another US company, PharmaJet, entered the market in 2009 with licensed MUNJIs..ElementAt(113,668), ElementAt(112,670) One project helped develop the high-speed Lectrajet (see Figure 61-6A), with its unique system for fingers-free loading and unloading of cartridges that permits vaccinating at least 600 persons per hour for mass campaigns, as well as a manual model sharing the same syringes for routine immunization that was found safe and immunogenic for influenza vaccination and was licensed in the United States in 2009 (see Figure 61-6B). Another set of contracts assisted in adapting Pharmajet technology for ID delivery, which was licensed in 2011 (see Figure 61-2). A third set of Small Business Innovation Research contracts supported R&D of the Zetajet (see Figure 61-6J), which was licensed in 2009 and once called the Vitavax. Its built-in hand-crank to wind its spring was a feature targeted for developing-country value.

PATH has also been a major player in this field, conducting its own R&D as well as assisting the companies developing the DSJIs mentioned here. In 2008, the Bill and Melinda Gates Foundation awarded PATH $9.8 million to enhance its close collaboration with industry to determine the value, appropriateness, extent of application, and regulatory pathways for DSJIs to deliver vaccines in developing-country immunization programs. PATH initiative for DSJIs has included sponsoring and coordinating key policy analyses on ID delivery (including by non-DSJI means), economic modeling, and clinical trials on multiple continents.

One project helped develop the high-speed Lectrajet (see Figure 61-6A), with its unique system for fingers-free loading and unloading of cartridges that permits vaccinating at least 600 persons per hour for mass campaigns, as well as a manual model sharing the same syringes for routine immunization that was found safe and immunogenic for influenza vaccination and was licensed in the United States in 2009 (see Figure 61-6B). Another set of contracts assisted in adapting Pharmajet technology for ID delivery, which was licensed in 2011 (see Figure 61-2). PATH initiative for DSJIs has included sponsoring and coordinating key policy analyses on ID delivery (including by non-DSJI means), economic modeling, and clinical trials on multiple continents.

Regulatory matters

In 2009, to prompt public comment before formal promulgation, the FDA published a draft guidance document on pen, jet, and related injectors intended for use with drugs and biological products. No similar prior effort to clarify the regulatory landscape for these devices had ever been published. Many existing devices, including all the MUNJIs, either had been grandfathered onto the market by virtue of preceding the 1976 cutoff date for medical device regulation, or were cleared for sale on the basis of “substantial equivalence” to such injectors (or to other “predicates” that had themselves been linked back to earlier devices). The draft document covered design and construction features, bench testing aspects, sterility and labeling issues, and most importantly, clinical testing.

Among the many docket submissions commenting on the draft, the most common observation was that the proposed guidance document did not distinguish sufficiently between the broad types of devices it covered—including DSJIs, MUNJIs, and pen (needle) injectors—and that their differences deserved distinctions in how they should be regulated in accordance with the “least burdensome” principle. For example, the same level of stringency for demonstrating the safety of MUNJIs because of their cross-contamination risk [as summarized in “Safety of multisyringe nozzle jet injectors,” earlier] was to apply also to DSJIs.

Another major critique of the draft guidance was its proposal that before licensure, device manufacturers should identify “the drugs/biologic products that are currently approved and marketed for the dosage, rate, and route of administration proposed for the general use injector”. As pointed out in PATH’s comprehensive docket submission, this might necessarily require them to conduct clinical trials for every drug or vaccine that a physician may decide to administer. It would thus pose a major obstacle for innovation and development of “general use” devices that are sold empty, that are not labeled or promoted for use with any particular drug, and that rely on the clinical judgment of the physician in practicing medicine in accordance with evidence in the scientific literature and any standards of care (as is the case for needles and syringes). This would apply even for off-label uses not specifically approved by the FDA for the drug involved, as the FDA itself has elegantly stated. As of June 2012, no formal promulgation of the guidance document has occurred.
On October 21, 2011, at the peak of the US influenza vaccination season, the FDA issued an unusual and surprising warning to physicians, without the usual advance notice and consultation with affected parties and agencies. It advised against the use of jet injectors to deliver influenza vaccines because there were “no data” substantiating such use. The effect was dramatic. Drugstore and grocery chains immediately cancelled orders for what was expected to be several million syringes and thousands of accompanying devices, putting at risk the survival of the small companies involved.

Within days, the FDA replaced the categorical statement on its website with a more nuanced one pointing out that it had not been provided any data from the manufacturers of the six then-current US-marketed influenza vaccines for delivery by JIs. It also cited “limited data” from two JJ studies (both conducted with CDC involvement) demonstrating similar immune responses to influenza vaccines administered by jet injectors and by needles, and therefore that “FDA and CDC believe that people who got their influenza vaccine via jet injector do not need to be re-vaccinated.”

The CDC’s Advisory Committee on Immunization Practices has for many years recognized jet injection as an effective method of vaccination, based on the substantial literature and experience reviewed in this chapter. It remains unknown whether such a standard of care for accepted public health and medical practice can restore a market for such off-label use, or whether vaccine manufacturers will undertake new studies and petition the FDA to add jet injection to their product labels. Thus, the future remains uncertain for the small businesses that constitute the global industry for the manufacture of safe, modern jet injector systems for vaccination.

### Respiratory vaccination

Since the very early history of immunization, the respiratory tract has been a promising route for vaccine delivery. However, only in 2004 did respiratory vaccines first become a part of routine modern immunization practice, with the licensure of an intranasal (IN), live attenuated influenza vaccine (FluMist) in the United States (see Chapter 18). The major potential advantages of respiratory immunization are that it avoids the risks and concerns associated with parenteral injection, and it generally provides stronger mucosal immunity than vaccination by that route. However, multiple obstacles (see “Challenges for respiratory delivery of vaccines,” later) have restricted wider application. As of 2011, FluMist was the only respiratory vaccine in general use. In contrast, the respiratory route is used to deliver a wide and expanding variety of pharmaceutical products.

The importance of mucosal immunity is that it prevents infection at the portals of entry for the great majority of human pathogens—the respiratory, gastrointestinal, and genitourinary tracts. In contrast, systemic immunity clears infection only after successful invasion, by limiting replication and destroying the pathogens. Ideally, both mucosal and systemic immunity should be raised against targeted pathogens. Strong mucosal immunity may enhance the benefits of immunization for some diseases. For example, by preventing the initial infection, mucosal immunity can reduce the risk of transmission to others, in addition to preventing clinical disease. Prevention of infection at the mucosal surface may be especially important for diseases for which effective systemic immunity has been difficult to achieve, such as tuberculosis and AIDS.

Every mucosal surface available for administering vaccines has been studied with a variety of antigens in animal models, including oral, respiratory, rectal, vaginal, and ocular tissues. Several human vaccines are already licensed and in successful use for delivery by oral ingestion, including those for polio, cholera, rotavirus, typhoid, and adenovirus (see relevant chapters in this book). Although vaginal and rectal vaccines may work, they would have limited acceptability for social, cultural, and practical reasons. The remainder of this chapter will cover only the upper and lower respiratory tract, focusing on device technologies for deposition into these tissues, optimal presentation of antigen to the respiratory immune system, and adjuvants to enhance its immune response.

### Antigen presentation and processing in the respiratory tract

#### Airborne particle entry and airflow

Like pathogens, respiratory vaccine antigens enter as airborne particles through the nares or mouth into airways designed to foil their entry and passage. Particles inspired through the nose are first filtered by the nasal hairs, and then they must traverse the external nasal valves, slit-like passages that limit airflow from the nares into the internal nasal airways. Djupesland and colleagues showed that only 25% of large, high-speed droplets [average, 43 μm] of a traditional nasal spray reach beyond the external nasal valve. This nasal filtration system may be bypassed by oral delivery via mask or mouthpiece. However, most large, high-speed particles are stopped in the mouth.

Small particles inhaled via nose or mouth share a common pathway through the oropharynx, larynx, and trachea. The bifurcation of the trachea into the right and left bronchi starts a series of bifurcations, providing further surfaces to trap airborne particles. Only very small, light, and slow-moving particles succeed in navigating the tortuous pulmonary passages to deposit in the lower airways. The smallest particles (≤ 3 μm) may reach the alveoli, where they can be rapidly absorbed into systemic circulation. The complex branching of the lung passages also results in an astonishing alveolar surface area, exceeding 100 square meters in a human adult male, compared with an average of only about 150 square centimeters (0.015 m²) in the nasal airways. The lower airways in humans do not typically have organized lymphoid tissues, but they do have abundant intraepithelial dendritic cells and alveolar macrophages that process antigens.

#### Particle deposition, movement, and uptake

In the internal nasal airway, particles deposit on the nasal mucosa covering the turbinates and then join the flow of mucus that is swept by ciliated epithelia toward the pharynx, where it is swallowed. Immune surveillance of antigens in the flow of mucus begins as they are taken up into epithelial cells, intraepithelial dendritic cells, surface macrophages, and microfold [M] cells. M cells are specialized epithelial cells that take up macromolecules, viruses, and bacteria by endocytosis, and then present them to lymphocytes and dendritic cells that congregate in invaginated pockets of the M cells, these pockets communicate with the extracellular space (see Figure 61-1B).

The predominant organized lymphoid tissue of the human respiratory tract is located in the pharynx, where the adenoids and other tonsils (collectively known as Waldeyer’s ring) surround the nasal and oral passages. The epithelium overlying these tissues is rich with M cells. Increasing the deposition of vaccine antigen in the posterior nasal passages and nasopharynx near Waldeyer’s ring may be desirable to maximize the immune response. Breath actuation of a nasal spray and nasal inhalation of smaller aerosol particles (5 to 20 μm) are two methods to increase nasopharyngeal deposition (see Figure 61-9A,B).

### Regional processing

Antigen-presenting cells from the respiratory tract drain to regional lymph nodes, where the B cells preferentially switch to IgA plasmablasts. These plasmablasts “home” back to the
SECTION THREE • Vaccines in development and new vaccine strategies

airway epithelium to provide antigen-specific IgA protection. T cells also play a major role in mucosal immunologic memory responses. Some lymphocytes exposed to antigen in the respiratory tract migrate to provide protection at remote mucosal sites, such as the vagina. This integrated network of immune cells and tissues is known as the common mucosal immune system. Because the respiratory tract is exposed to a myriad of nonpathogenic macromolecules, there are mechanisms for downregulating the immune response to antigenic exposure. This immunologic tolerance must be considered when developing respiratory immunization strategies.

Challenges for respiratory delivery of vaccines

Identifying target tissues

The first challenge in respiratory immunization is determining the appropriate target tissues. Most respiratory drugs traditionally target two areas. For example, the nasal passages are the desired site of action for decongestants, and the lower airways are targeted for asthma medications. The optimal target tissues are not yet understood for most potential respiratory vaccines, and they vary for different antigens. The pharyngeal tonsils are likely candidate targets because of their key role in immunologic priming, but some vaccines may require deposition in the lower airways for uptake by alveolar macrophages and dendritic cells. Scientific methods for evaluating and comparing different target tissues are not yet well developed.

Applying animal models

A second challenge is the difficulty in selecting animal models and extrapolating their results for human respiratory vaccine delivery. Interspecies differences in respiratory immunologic tissue organization limit interpretation of animal target-tissue research results for humans. Moreover, the size and anatomy of the respiratory tracts of common research animals differ greatly from those in humans. For example, in small animals such as rodents, nose drops may deposit to the entire respiratory tract, which would not be the case in humans. Balmelli and colleagues estimated that 30% of 20 μL of vaccine given to mice as IN drops deposited into the lungs.

Many viruses and bacteria that infect humans do not grow well in animal models. For example, species-specific differences in the distribution of sialic acid receptors on cell surfaces is a crucial factor in tissue and host specificity of influenza A viruses, which limits the number of animal models suitable for influenza research. Species-specific differences can make it difficult to use animals to study attenuated live vaccines or vaccine vectors, as well as to challenge animals to assess protection. This impedes the development of safe and effective respiratory vaccines for humans.

Delivering consistent dosages

A third challenge for respiratory immunization is dosage accuracy. The mass or volume of the antigen delivered depends on many factors, including variability in performance by the respiratory delivery device, the behavior and technique of the person administering the vaccine, and differences in the anatomy and physiology between vaccinees (animals) or vaccinees (humans). Fortunately, for many vaccines there is a wide margin between the dosage necessary to induce protection and the dosage at which the risk of adverse events increases.

The licensure in 2006 in the United States and Europe of the first inhalable insulin (Exubera), a drug for which dosage accuracy and consistency is critical, suggests that this challenge can be overcome for respiratory vaccines. However, the commercial failure of Exubera poses a cautionary example for developers of potential aerosol vaccines. The product was withdrawn from the market in 2007 by the manufacturer because of lack of sales, after nearly $3 billion was invested in development and licensing. The major reasons cited for this market failure were patient and physician concerns about long-term safety, complexity and size of the delivery device, increased cost compared with injection, and the availability of newer injection devices such as insulin pens.

Predicting protection from immune response

A fourth major challenge is the lack of accepted correlates of protection of mucosal immunity. In contrast, for many diseases there are laboratory assays to measure well-established criteria for systemic immunity—such as antibody titters above certain cutoffs—that have served for many years to predict protection from disease. In the absence of accepted serologic or cellular correlates of protection induced by mucosal vaccines, clinical trials must use specific disease-prevention endpoints, which can make the studies much larger and more expensive.

Ensuring safety

Several immunization safety issues represent further challenges for respiratory vaccines. One is the risk that vaccine antigen (live or inactivated), adjuvant, or excipients might affect nearby cranial nerves, or might travel along the olfactory nerve through the cribriform plate into the brain, with resulting adverse central nervous system effects. Vaccines targeting the lower airways may induce or exacerbate bronchospasm or pulmonary inflammation, which can be life threatening. Another risk is cross-contamination: respiratory pathogens from one patient may contaminate the respiratory immunization device and be spread to subsequent patients. Also, vaccine aerosols may spread beyond the intended vaccinee and affect other persons in the vicinity. Finally, live virus or bacterial vaccines might pose an increased risk to immunocompromised persons if delivered via the respiratory tract.

Designing practical delivery techniques

Remaining challenges relate to the delivery devices. Although many already exist for delivering drugs to the respiratory tract, they are not designed for vaccines. Most respiratory drug devices deliver repetitive doses to a single patient. In contrast, the expected usage for vaccination devices is to deliver single doses to multiple patients, which raises the cross-contamination issue. Although single-use, disposable devices or device components could solve this problem, they must be inexpensive to be cost effective. Some aerosol-drug delivery devices require patient education to obtain the needed cooperation for adequate dose delivery. This may be difficult in the brief time typically involved in vaccination. In young children, who receive many vaccines, some respiratory delivery methods are not effective.

Although current respiratory drug delivery devices typically target the anterior nasal passages or the lower airway, respiratory vaccination may work best in the quite different target of the pharyngeal tonsils. In theory, ideal nasal delivery devices would prolong effective antigen presentation by depositing over a large surface area in the internal nasal airway, allowing mucus flow to move vaccine gradually across the tonsils.

Advancing the art

New delivery technologies to achieve respiratory immunization are required if this route is to become practical and accepted. As a young field, published research is limited on relevant devices in animals or humans. In most reported animal studies, the delivery device is not mentioned at all, or a laboratory pipette was used for intranasal instillation, which would be unsuitable for humans. For most respiratory devices designed for humans, testing is very difficult or impossible in an animal model.
Alternative vaccine delivery methods

Last, perhaps the most significant challenges to implementation of respiratory vaccination and other novel vaccine delivery systems in routine immunization practice are the regulatory requirements needed to ensure that the novel systems are safe and effective. The studies and clinical trials needed can be extremely expensive. Vaccine manufacturers are typically reluctant to assume such cost and risk to relaunch an existing product already delivering profits, unless the potential benefits and market advantages would be significant. The best opportunity to bring alternative delivery into routine practice may be to use new delivery systems from the start for new vaccines early in their development and licensure process.

Current progress in respiratory tract vaccination

Wet versus dry aerosols

Vaccines can be delivered to the respiratory tract directly as either liquid or dry-powder aerosols. All currently licensed vaccines (for injection, or for oral or nasal delivery) are either stored and administered as a liquid, or stored in dry form and reconstituted to a liquid just prior to administration. Delivery of liquid aerosols is thus closer to usual practice. It is also generally easier to perform animal studies by generating aerosols from existing liquid formulations. Dry aerosols require changes in the formulation and manufacture of the vaccine to achieve and sustain vaccine potency and powder dispersability. If these challenges can be met, dry aerosols have several advantages over liquid aerosols (see “Dry-powder formulations for respiratory delivery”, later).

Respiratory vaccination devices

AccuSpray™ nasal sprayer

The only device currently licensed and in use in the United States for respiratory vaccine delivery is the AccuSpray, which is used for FluMist live attenuated influenza vaccine [LAIV]. The device is a sterile, single-patient-use, disposable, prefilled glass syringe fixed with a nonremovable plastic nozzle (Figure 61-7C,D). Its total dose is 0.2 mL, of which 0.1 mL is sprayed consecutively into each nostril. An attachment on the plunger tells the user when to switch nostrils. FluMist vaccination delivered by AccuSpray is highly effective in most populations (see Chapter 18).

Key advantages of AccuSpray delivery are simplicity of use, low cost, disposability outside of sharps waste, and difficulty to refill and reuse. The large particle sizes generated by the sprayer minimize deposition to the lower airways, reducing the risk of adverse pulmonary events. A limitation of the system is that the particle size emitted depends on the speed at which the vaccinator depresses the plunger. The median diameters of the particles can range from 200 μm or greater at plunger speeds of up to 33 mm/sec, to 50 μm or less at speeds of 80 mm/sec and greater. Although this wide variability might in theory affect the efficiency of vaccine deposition, LAIV by AccuSpray produces a high rate of protective immunity at the current dosage of 10^6 fluorescent focus units for each of the three strains included in the vaccine.

To assess the potential of IN administration of measles vaccine, Simon and coworkers conducted a clinical trial with live attenuated (Moraten Berna) measles vaccine using the

Figure 61-7 Selected Devices for Respiratory Delivery of Liquid Aerosol Vaccines. (A) and (B) Investigational Classic Mexican Device for aerosol vaccine delivery, illustrated by component diagram (A) and use in clinical trials (B). A nonmedical electric compressor (not shown) delivers roughly 9 L of air per minute at a pressure of 30 to 40 psi (207 to 276 kPa) to a jet nebulizer that is kept in crushed ice to maintain vaccine potency. The vaccine aerosol (roughly 0.15 cm³ of particles averaging 4.3 μm in diameter) is delivered through a disposable paper cone held close to the patient's face for 30 seconds. From Valdespino-Gómez JL, de Lourdes García-Garcia M, Fernandez-de-Castro J, et al. Measles aerosol vaccination. Curr Top Microbiol Immunol 304:165-93, 2006 (Fig. 1, p. 169). (C) and (D) AccuSpray nasal spray syringe (Becton, Dickinson and Co.). Produces an aerosol plume of particles reported from 50 to 200 μm in diameter, depending on plunger speed. AccuSpray used for intranasal delivery of FluMist influenza vaccine (MedImmune, Inc.). Prefilled liquid vaccine is stored refrigerated for single patient use. The total volume is 0.2 mL. A dose separator interrupts delivery at 0.1 mL and, when reset, allows the remaining 0.1 mL to be administered into the opposite nostril. (E) and (F) Investigational AeroVax prototype (AerovectRx, Inc.) developed by Centers for Disease Control and Prevention and Creare, Inc. The nebulizer utilizes battery-powered piezoelectric energy to drive an aerosol from a disposable drug cartridge via a microperforated mesh plate through a disposable patient interface, such as (F) nasal prong in patient nostril, oral prong, or mask (not shown). Droplet diameters can be tailored from < 5 μm to 10 to 25 μm for upper or lower airway delivery, respectively. (Figure 61-7A, courtesy of José Luis Valdespino (Instituto Nacional de Salud Pública, Mexico); 7C, D, courtesy of Nuphar Rozen-Alder [Becton, Dickinson and Co.]; 7E, F, courtesy of James Gathany [CDC Photographic Services].)
SECTION THREE • Vaccines in development and new vaccine strategies

AccuSpray. IN administration produced protective serum antibody titers in only 50% of nonimmune individuals, compared with protective titers in 100% of volunteers who received the vaccine by the SC route.774 Notably, IN vaccination resulted in increased production of measles-virus-specific secretory IgA (sIgA) in oral fluid and nasal washes among previously nonimmune individuals, but without evidence of a systemic immune response.775

Classic Mexican Device nebulizer

Another respiratory immunization device that has been used in humans is the jet nebulizer system known as the Classic Mexican Device (CMD, see Figure 61-7A,B). With slight modifications, this nebulizer system was used to deliver live attenuated measles vaccines in multiple clinical trials in Mexico and South Africa, and also to vaccinate over 3 million Mexican children against measles in a mass campaign.776–779 The system consists of a general-use [non-medical-grade] compressor that delivers air to a jet nebulizer [from iP780,781, which holds the vaccine in a crushed ice to maintain potency during the vaccination session. The vaccine aerosol is delivered through reusable plastic tubing to a single-use, disposable paper cone [modified from a drinking cup], which is held close to the patient’s face for 30 seconds. Typically, the aerosolized dose volume is roughly 0.15 mL, and the mass median aerosol diameter of droplets is 4.3 μm.782 In a recent study by Bennett and colleagues, the dose for each child was delivered from the CMD into a single-use, disposable plastic bag to avoid the risk of cross-contamination of the tubing. This reservoir was then separated from the tubing before the child inhaled its contents via a one-way valve mask. Preschool-age children vaccinated from the aerosol reservoir developed higher antibody GMTs than did subjects vaccinated by the SC route.783 In a study that assessed the distribution of viable vaccine virus across the range of droplet sizes emitted from a CMD, Coates and coworkers estimated that 30% of infective viral particles were contained in droplets with diameters of 5 μm or less, and 23% were in droplets of greater than 10 μm.784

Although the CMD has demonstrated a level of safety and immunogenicity, it is heavy, cumbersome, noisy, and requires outlets (mains) electricity and crushed ice. It is thus not practical for routine vaccination.

Measles Aerosol Project nebulizer

Because of the encouraging results of early measles aerosol vaccines (see ‘Classic Mexican Device nebulizer’, earlier, and ‘Live viruses’, later), in 2002 the WHO, in partnership with the CDC and the American Red Cross, initiated the Measles Aerosol Project (MAP). Its goal is licensure of at least one live attenuated measles vaccine and its associated aerosol delivery system in the developing world.785 The project documented immunogenicity and safety [ie, the lack of local or systemic toxicity] in animal studies.786 Three existing therapeutic nebulizers were used for phase 1 clinical trials: the AeroEclipse,787 the ComPair,788 and the Aeroneb.789 The selection criteria were [1] critical performance data, [2] usability under field conditions, [3] vaccine potency during nebulization,789 and [4] existing licensure for other uses. Measles vaccine delivery by the three devices, delivered to 145 subjects in India, was reported to be safe, well tolerated, and immunogenic.790

A modified version of Aeroneb device was selected for use in the phase 2/3 pivotal trial initiated in 2009 by the MAP.791 The study was a randomized, open-label, active-control, non-inferiority trial of the measles vaccine in unvaccinated healthy infants from 9 to 11.9 months of age. As of November 2011, study results had not been released or published.792

Other aerosol devices studied in vaccine research

The OptiMist is a breath-actuated nasal-spray device that delivers liquid or dry-powder aerosols only during oral exhalation.793 Because this raises the soft palate to close the connection between nose and throat, pulmonary deposition is avoided, and delivery to the posterior nasal segments is increased (see Figure 61-9A,B).794 In a human study, inactivated influenza vaccine self-administered using the OptiMist resulted in significant increases in virus-specific IgA in nasal secretions, as well as protective levels of virus-specific serum antibodies, after two doses in more than 80% of subjects.795

A Combitrips Plus pipette dispenser796 was used to deliver a dry-powder Neisseria meningitidis IN vaccine to human subjects. Those vaccinated by the IN route had serum bactericidal antibody titers comparable to that of those vaccinated by conventional injection, and 92% of IN vaccinees had protective titers after the second dose. One third of IN vaccinees reported mild side effects, compared with the two thirds of injection vaccinees who reported mild injection pain.797 Another dry-powder inhaler, the single-use, disposable ’Dioncer’798 (Figure 61-8E) dispersed an insulin-based dry-powder subunit influenza vaccine with an aerodynamic particle size distribution suitable for pulmonary administration.797,798

Two unique dry-powder delivery devices, the PuffHaler799–801 (see Figure 61-8A,B) and the Becton, Dickinson (BD) Solvent® (see Figure 61-8C,D), were developed and tested as part of an initiative to develop a measles vaccine dry powder (MVDP). The project is led by Aktiv-Dry, LLC799 [see ‘Dry-powder formulations for respiratory delivery’, later]. Each device disperses MVDP into an inexpensive, single-use, disposable reservoir from which the patient inhales, eliminating the risk of cross-contamination. After successful demonstration in the cotton- rat model,802 MVDP was evaluated in rhesus macaques using PuffHaler and BD Solvent via mask and via the direct IN route from the devices.803 Respiratory delivery induced robust, significant measles-specific humoral and T-cell responses with no adverse effects. When challenged more than 1 year later, the MVDP-vaccinated macaques were protected from infection with wild-type measles virus.804 In other studies, the BD Solvent was effective for direct nasal delivery of influenza vaccine to rats, and of anthrax vaccine to rabbits.805–807

The CDC developed the AeroVax nebulizer (see Figure 61-7E,F), in collaboration with Creare, Inc.22,805 It utilizes a disposable patient interface (nasal prong, oral prong, or mask) and a disposable drug cartridge to prevent cross-contamination. Disposable drug cartridges can be manufactured to generate custom particle size distributions (eg, 10- to 25-μm droplets for upper-airway delivery, or droplets of 5 μm or less to reach the lower airway). Delivery of live attenuated measles vaccine via nasal prong was shown to be safe and immunogenic in macaques.808

A 15-second aerosol delivery by the AeroVax device of influenza virus X31 induced a robust immune response in mice, which protected them against homologous (X31) and heterologous [PR8] influenza challenge.809 Nasal aerosol delivery of LAIV to ferrets elicited high levels of serum neutralizing antibodies and protected them from homologous virus challenge at conventional (median tissue culture infective dose [TCID50]).101 and significantly reduced (TCID50).101 dosages, and provided a significant level of subtype-specific cross-protection.102 AerovectRx, Inc.102 acquired the rights to manufacture and distribute this technology.

An investigational device for nasal delivery of dry-powder vaccine to nasopharyngeal tissues only was developed by the CDC and Creare, Inc.103 (see Figure 61-8F). It operates by patient exhalation through the mouth, blowing the powder into the nose while simultaneously generating air flow that limits entry to the lower respiratory tract. Its deposition pattern to targeted nasal tissues was documented in three-dimensional plastic models developed by CFDRC, Inc.,104 from in vivo computerized tomography of a child’s head (Figure 61-9C,D, and see Figure 61-8F).
Delivery vehicles for vaccination via the respiratory tract

Once the device has delivered vaccine to the appropriate region of the respiratory tract, sufficient quantities of the antigen (and adjuvant if needed) must penetrate mucosal or alveolar barriers to gain access to appropriate cells to activate the immune system. The vehicles or vectors that can be used for this purpose include live attenuated viruses (including those acting as vectors for exogenous antigens), live attenuated bacteria (including vectors), commensal bacterial vectors, virosomes, virus-like particles (VLPs), liposomes, lipoproteins, immune stimulating complexes (ISCOMs), microparticles, and nanoparticles.610–614

Live viruses

Viruses are prototypical antigen-delivery vehicles because they enter and commandeering cells to replicate themselves, thus multiplying the available antigen that they encode. Also, viruses can induce a natural adjuvant effect through activation of chemokines and cytokines. The most widely studied respiratory delivery vehicles are live attenuated strains of pathogenic viruses.615–617 Their major risks are possible reversion to virulence, potential neurotoxicity via the olfactory route, and potential pathogenic effects in immunocompromised persons.

Influenza

Cold-adapted LAIV [FluMist]618 is the only vaccine currently licensed in the United States for delivery by the IN route. Its development, testing, and licensure are reviewed in detail in Chapter 18. LAIV delivered by the IN route demonstrates several potential benefits of this method. It produces both mucosal and systemic immunity, and it provides higher protective efficacy than injected inactivated vaccine in young children.618–621 It provides heterotypic immunity against influenza strains that had antigenically drifted from the vaccine strains.621–622 It may reduce the risk of influenza transmission because it reduces respiratory shedding among immunized children challenged later with a vaccine virus.623–625 Finally, modest coverage with LAIV among school children reduced influenza-related illness rates in unvaccinated adults in a community.626

Figure 61-8 Selected Devices for Respiratory Delivery of Dry-Powder Aerosol Vaccines. (A) Investigational PuffHaler dry-powder inhaler (Aktivdry, LLC). Air from the empty bulb loosens vaccine powder from the dispenser into the reservoir once the pressure threshold of the burst valve is exceeded. (From Kisch KO, Higgins MP, Park I, et al. Dry powder measles vaccine: particle deposition, virus replication, and immune response in cotton rats following inhalation. Vaccine 29:966-972, 2011 [Fig. 1, p. 967].) (B) Patient inhales from the single-use-only reservoir of PuffHaler after detachment from the device, either directly (as shown) or via a disposable mask (not shown). (From Lay J. The man fighting measles one breath at a time. Coloradoan Magazine [University of Colorado, Boulder], March 2011, [photo, p. 10, by Glenn Arakawa].) (C) Investigational Solovent dry-powder inhaler prototype (Becton, Dickinson and Co.). Air from the empty syringe ruptures the membranes of the vaccine container, releasing into the cardstock spacer a plume of dry powder. Patient inhales from the cardstock spacer directly, or via a mask. The vaccine container (capsule), spacer and mask are single-use disposables. (D) Plume of powder upon release from Solovent in open air for visualization purposes. (E) Investigational T wincer single-use, disposable, dry-powder inhaler for pulmonary delivery (University of Groningen). The drug formulation (capsule), releasing into the cardstock spacer once the pressure threshold of the syringe is reached, is stored in the snap-together plates of the device in an aluminum blister for maximal moisture protection. The powder becomes available for inhalation upon pulling a foil cover that protrudes from the rear of the inhaler (not shown). (F) Investigational nasal dry powder inhaler developed by CDC and Creare, Inc. A prefilled cup (shown between right thumb and forefinger) containing the powdered vaccine is opened by its attachment to the device. The breath of the patient blowing into the device tube carries the dry powder into the nose. In theory, dispersion during patient exhalation limits pulmonary deposition from the posterior nasal space. The plastic face is a phantom model of the airway of a 5-year-old child constructed according to in vivo computerized tomography (CFDRC, Inc.). (Figure 61-8A, courtesy of Scott Winston [Aktivdry, LLC]; 8B, courtesy of Glenn Arakawa [University of Colorado]; 8C, courtesy of Becton, Dickinson and Co. [Kenneth Powell]; 8D, courtesy of Becton, Dickinson and Co. [Vincent Sullivan]; 8E, courtesy of University of Groningen [A. H. de Boer]; 8F, courtesy of Darin Knaus [Creare, Inc.].)
Measles

After influenza, measles is the next-most-studied disease for vaccine delivery via the respiratory tract, pioneered by Albert Sabin in the later years of his career. This evidence base prompted the Measles Aerosol Project, described earlier. Reviews and meta-analyses of multiple clinical studies revealed three basic immune-response patterns after measles vaccination.

First, drops or sprays delivered to the conjunctiva, or to the oral or nasal mucosa, produced inconsistent immune responses. Second, delivery of small-particle liquid aerosols via pulmonary inhalation to children 10 months of age or older typically produced immune responses in very high proportions of subjects. These responses to aerosol vaccines were usually equivalent to or greater than the responses to injected vaccines. For example, Dilraj and colleagues found that 96%, 94%, and 86% of schoolchildren who received the aerosol measles vaccine had antibody titers of greater than 300 IU/mL at 1, 2, and 6 years after vaccination, respectively, compared with 91%, 87%, and 73% among injected vaccinees.

The third pattern noted was generally lower immune responses for the aerosol route, compared with parenteral injection, among children younger than 10 months. For example, Wong-Chew and coworkers found vaccination of 12 and 9 month old infants by injection induced immunity in 100%, but by aerosol route in only 86% and 23%, respectively. One hypothesis was that the very low respiratory minute volume of young infants results in too small a dose of aerosol vaccine in that period of time. A follow-up study by Wong-Chew and colleagues demonstrated that increasing exposure time to aerosol measles vaccine elicits immune responses that are comparable to those seen when an equivalent dose is administered by the SC route in 9 month old infants.

With regard to vaccine safety, the same reviews and meta-analyses noted that no severe adverse events were reported after aerosol measles vaccination in any of the studies. Rates of minor adverse events, when reported, have typically been less than or the same as vaccination by injection. Experience in mass campaigns was similar, with de Castro and colleagues reporting no serious adverse events among more than 3.7 million children in Mexico vaccinated by aerosol.
Rubella and mumps
IN delivery of live attenuated rubella vaccine was investigated during the 1970s in many clinical trials. Ganguly and coworkers demonstrated that IN drops or spray of vaccine virus produced mucosal IgA antibody, equivalent serum IgG antibody, and better protection against reinfection compared with SC vaccination. The subjects who received the IN challenge, however, had higher rates of mild adverse events, usually rhinitis and sore throat.

In more recent studies, Bennett and colleagues found that aerosol vaccination of preschool children with a combination measles-mumps-rubella vaccine produced antibody responses to rubella and mumps equivalent to those produced by injection. Sepulveda and coworkers found that aerosolized measles-rubella combination vaccine in school-age children not previously vaccinated against rubella produced high levels of rubella immunity, equivalent to that seen after SC injection. Fewer adverse events were reported in the aerosol group. Diaz Ortega and colleagues found that measles-mumps-rubella vaccination by aerosol in college students produced immune responses similar to those produced by injection, with seropositivity retained in all vaccinees 1 year after vaccination.

Live viruses as vector vaccines
Recombinant viruses acting as vectors by incorporation of a gene expressing a heterologous antigen have advantages similar to those of conventional attenuated live virus vaccines. They deliver the genetic code for the antigen into cells, and it is replicated to activate the immune system. Viruses used as vaccine vectors should, ideally, have very low pathogenic potential, even in immunocompromised people, as well as the capacity to incorporate the necessary foreign genes for desired antigens, promoters, and adjuvants.

Viruses that naturally infect or grow in respiratory tissues are especially well suited as vectors for respiratory immunization. Some studied in animal models include adenoviruses, alpha viruses, poxviruses, baculovirus, vesicular stomatitis virus, and adenov-associated virus. Adenovirus vectors delivered IN in several animal models produced immune responses against many diseases. For example, defective-complex adenovirus containing Ebola virus genes protected nonhuman primates against aerosol challenge with two Ebola species. Vaccinia strains such as modified vaccinia Ankara (MVA) have also been used effectively as vectors for respiratory immunization. An MVA vector expressing an HIV-1 antigen induced, by the IN route, antigen-specific mucosal CD8+ T cells in genital tissue and draining lymph nodes of mice, along with serum and vaginal antibodies.

One caveat for the use of vectored vaccines is that preexisting immunity in the population to the vector virus, either by natural exposure or by previous use in another vaccine, may reduce its effectiveness. However, Song and colleagues reported a series of studies in which adenovirus-vectorized vaccines delivered as a fine aerosol to the lungs produced strong immunogenicity even in animals with preexisting anti-adenoviral immunity, suggesting that pulmonary delivery may overcome this limitation to viral vector vaccines.

Live bacteria
Animal models of respiratory immunization have been used to study attenuated respiratory pathogen vaccines such as Mycobacterium bovis (BCG) and attenuated Bordetella pertussis, as well as nonrespiratory pathogens such as Salmonella and Shigella acting as recombinant vectors. Mouse studies also demonstrated an improved immune response to conventional BCG vaccine delivered by the IN route or by aerosol inhalation, compared with injection. The studies that included a challenge found that the respiratory route provided better protection than injection. Attenuated M. tuberculosis has also been immunogenic by the respiratory route.

As vectors, bacteria have an advantage over viruses because of their higher capacity for insertion of the heterologous genes expressing antigens, adjuvants, or plasmids for DNA vaccination [see next section]. Recombinant BCG has been used to express various heterologous antigens, including simian immunodeficiency virus, Borellia burgdorferi, and Streptococcus pneumoniae. Live attenuated Bordetella pertussis vaccine delivered by the IN route protected mice from Bordetella challenge. Similar IN delivery of recombinant B. pertussis expressing antigens of Clostridium tetani, H. influenzae, N. meningitidis, and Schistosoma mansoni induced strong immune responses in mice.

Attenuated recombinant Salmonella vaccines produced strong immune responses against a wide variety of pathogens when delivered by the IN route to rodents. Similar results were reported for IN Shigella vectors carrying enterotoxicogenic E. coli and tetanus genes. Commensal bacteria such as food-grade strains of Lactococcus, Lactobacillus, and Streptococcus gordonii have also been explored as vaccine vectors. Bacillary expression of adjuvants such as cholera toxin B, interleukin (IL)-6, and IL-12 has been shown to increase the immune response to respiratory vaccines.

A potential risk of administering live microbes was revealed in mice that developed dosage-dependent granulomatous BCG infiltration of the lungs after IN but not SC vaccination of BCG. As with viruses, preexisting immunity to the bacterial vector may diminish the immune response.

DNA vaccines
DNA vaccination involves the delivery of eponymous plasmids directly into host cells to express the desired antigen. Delivery of naked DNA to the respiratory tract as a vaccine has been studied in animal models for many diseases. For example, Kuklin and associates found that nasal delivery of a herpes simplex DNA vaccine generated higher levels of vaginal IgA than by the IM route, although the IM vaccine produced stronger serum antibodies and better protection against challenge. Live attenuated bacteria, especially Salmonella and Shigella, have been vectored to produce DNA for IN vaccination. For example, cotton rats vaccinated with attenuated Salmonella vaccine expressing DNA encoding for measles antigens resulted in significant reduction in measles virus titers in lung tissues after challenge.

Virosomes, liposomes, and microparticles as carriers of vaccine antigens—discussed next—have also delivered DNA by the respiratory route.

Non-replicating vaccine delivery systems
Synthetic constructs, including liposomes, virus-like-particles (VLPs), virosomes, immunostimulating complexes (ISCOMs), microparticles, and nanoparticles, are nonreplicating delivery systems that mimic live viruses in how they appear to the immune system to enhance antigen delivery (they may also carry adjuvant). Their terminology is not mutually exclusive and some terms are used synonymously. The particles are about the same size as viruses, allowing similar uptake by antigen-presenting cells. Many include a lipid component to increase cell membrane permeability, and they may contain unrelated viral or bacterial proteins to activate the immune system.

Liposomes are vesicles composed of a phospholipid bilayer membrane. Antigen can be covalently attached to the lipid bilayer, or on the outside of the membrane. A liposomal HIV-1 vaccine delivered to mice by the IN route resulted in strong IgG and IgA responses in serum and vaginal washes. VLPs are aggregates of viral proteins that may include a lipid component. IN vaccination of VLPs with influenza antigens similar to those of the 1918 pandemic strain protected mice and ferrets from lethal 1918 and H5N1 influenza virus challenge.
Virosomes have lipid bilayer membranes with embedded viral proteins and resemble viruses except that they lack the genetic material needed to replicate. Cusi and coworkers vaccinated mice by the IN route with a reconstituted influenza virosome assembled with plasmids expressing the carcinoembryonic antigen (CEA) gene. The intranasally vaccinated mice developed CEA-specific antibodies but were not protected from challenge with CEA-expressing mastocytoma cells. However, when the CEA virosomal vaccine was coadministered by the IN route with reconstituted influenza virosomes with plasmids expressing the CD40L gene as an adjuvant, the level of antibody increased and the mice were protected from tumor-cell challenge.

ISCOMs are cage-like structures roughly 40 nm in size, composed of 12 subunits of saponin (such as Quil A) and cholesterol. Several antigens administered in ISCOM-based IN vaccines produced strong systemic and mucosal immune responses. For example, IN administration of ISCOMs with a tuberculosis recombinant protein strongly boosted prior BCG immunity and reduced bacterial burden in the lungs compared with nonbooster mice.

Respiratory delivery can also be enhanced by packaging antigens and adjuvants into microparticles or nanoparticles composed of polymers of biodegradable materials such as polylactide (PLA) and polylactide co-glycolide (PLGA), or into bio-polymers such as chitin or chitosan. Microparticles can be designed to slowly release antigens to increase the duration of antigen presentation. Carcaboso and colleagues reported that mice immunized by the IN route with a synthetic malaria vaccine encapsulated into 1.5-μm-diameter microparticles of PLGA had significantly higher antigen-specific serum IgG titers than control mice given the vaccine by the SC route with alum adjuvant. Pulmonary immunization with chitosan microparticles containing diphtheria toxoid resulted in neutralizing antibody titers comparable to or significantly higher than those achieved after SC administration of alum-adsorbed diphtheria toxoid.

Dry-powder formulations for respiratory delivery

Vaccines based on any of these delivery systems could potentially be formulated into powders for direct delivery in the dry state, a technique for which there is growing interest. For example, a PubMed search in October 2011 using the terms vaccine and powder yielded 33 articles published since 2000, related to respiratory delivery of powder vaccines, compared with only two prior to that year.

A number of obstacles must be overcome to produce successful respirable vaccines as dry particles of the sizes suitable for delivery to the respiratory tract. First, formulating powders requires significant and extensive changes in manufacturing methods, even from those used for current lyophilized vaccines. Second, many potential dry formulation ingredients are extremely hygroscopic and burn up when exposed to humidity. Engineering is needed to maintain their structure and dispersability for delivery in the dry state. Third, once the powders are deposited in the respiratory tract, they must be sufficiently hygroscopic to dissolve and release the vaccine for uptake.

Another challenge is that most dry-powder delivery devices require active inhalation by the patient and thus may be impractical for small children. Two potential solutions for this age group, however, are direct nasal delivery, as well as dispensing the powder into a reservoir [see, eg, Figure 61-8A,B] from which the child can breathe normally.

On the other hand, there are several significant potential advantages to dry-powder vaccination. Doses can be filled into inexpensive, single-use presentations and delivered without on-site aqueous reconstitution, thus avoiding the occasional human error that results in using the wrong or contaminated diluent. The cost of shipping and storing such diluents would be avoided. Secondary packaging that seals the dose container in an impermeable overwrap, such as metal foil, could maintain low humidity, which may prolong potency and increase shelf life. Recent progress for improving the thermostability of liquid vaccines, and even more so for dry ones, points to a future in which many vaccines may not require a cold chain.

Measles vaccine powders

Measles vaccination has been a path-finding application for respiratory delivery of dry powder. Early formulations were finely milled and retained adequate potency, but immune responses were poor when delivered to the respiratory tract of macaques. An active developer is Aktiv-Dry, which is working with partners including the Serum Institute of India (SII), the CDC, and the University of Colorado. In 2005, its MVDP project was awarded over $19 million in a Grand Challenges in Global Health grant from the Bill and Melinda Gates Foundation to refine a formulation, establish dry-powder measles vaccine production capacity at SII, and complete animal and phase 1 clinical testing.

Aktiv-Dry uses a novel spray-drying system to manufacture inhalable MVDP, starting from a bulk liquid of SII-provided, live attenuated antigen containing myo-inositol as a stabilizer. Virus plaque assays demonstrated potency losses in the drying process of 0% to 22%, which is comparable to losses seen with lyophilization. As reported earlier, the end product demonstrated immunogenicity in cotton rats and rhesus macaques. Its licensure-grade toxocolgy study found no test-article-related effects, or delayed onset of toxicity after inhalation by Sprague-Dawley rats. A second toxocolgy study after administration by mask using either BD Soloven or PuffHaler to measles-seronegative rhesus macaques produced no effects in mortality, clinical observations, respiratory function, clinical pathology, or histopathology.

SII manufactured MVDP, and its clinical trial application was approved by the Drug Controller General of India to conduct a phase 1 safety trial in adults, adolescents, and infants using the PuffHaler or BD Soloven devices. The trial began in May of 2012.

A separate project, reported by Ohtake and coworkers, found that a dry-powder measles vaccine, made by mild spray-drying and with unique stabilizers, was stable for up to 8 weeks at 37°C.

Influenza vaccine powders

Dry-powder vaccines for influenza have been formulated and tested by several groups. A whole, inactivated virus product delivered by the IN route in rats elicited high titers of nasal anti-influenza IgA, as well as serum antibody titers equivalent to those obtained with injected vaccine. No loss of potency was found when it was stored at 25°C and 25% relative humidity for up to 12 weeks, and at 40°C and 75% relative humidity for 2 weeks.

Another formulation produced by spray-freeze drying, with subunit viral antigen and inulin stabilizer, induced, upon pulmonary delivery, humoral (IgG), cell-mediated (IL-4, interferon gamma), and mucosal (IgA, IgG) immune responses in BALB/c mice. The pulmonary route for a spray-dried vaccine was evaluated, with inactivated virus vaccine stabilized with inulin provided protection similar to that provided by IM injection of mice exposed to a lethal dose of live virus.

Powder formulations for other vaccines

Other human-disease targets for dry-powder delivery studies include tuberculosis, hepatitis B, norovirus gastroenteritis, anthrax, and plague. A spray-dried formulation of adenovirus-vectorized tuberculosis antigen with mannitol-based stabilizers was shown to have characteristics suitable for...
pulmonary delivery in terms of thermodynamics, water absorption, particle size distribution and morphology, and virus survival. 1043 Nanoparticle-aggregate formulations containing recombinant hepatitis B surface antigen administered to the lungs of guinea pigs produced high IgG and IgA titers. 1044 Nasal vaccination with Norwalk-virus VLPs with an inert in situ gelling polysaccharide induced systemic and mucosal antibody titers equal to or greater than those achieved by VLPs plus adjuvant in a liquid formulation delivered by the IN route. 1045 Dry-powder vaccines against bioweapons threats have been studied. For example, anthrax vaccine by the IN route provided complete protection against inhalational challenge with roughly 90 times the median lethal dose [LD₅₀] in rabbits, while providing better stability than liquid formulations. 1046–1048 A stable powder vaccine against Yersinia pestis administered by the IN route to mice required but an extra dose of vaccine to achieve protection similar to that of IM delivery against plague after lethal challenge. 1049

Adjuvants for respiratory delivery

Nonreplicating adjuvants delivered via the respiratory tract are typically poorly immunogenic and may require adjuvants to stimulate an appropriate immune response. Adjuvants studied for this purpose include bacterial toxins and their derivatives, other bacterial components, bacterial DNA motifs, cytokines and chemokines, plant derivatives, and nanoemulsions. 1051–1056

Toxins

Cholera toxin (CT) and E. coli heat-labile toxin are potent adjuvants, but in native forms they may be too toxic for some uses in humans (see “Bacterial exotoxins”, earlier). 1053, 1057–1058 LT adjuvant in a commercial Swiss influenza vaccine for IN delivery was suspected as the reason for a many-fold increase in the risk of Bell’s palsy after vaccination, leading to market withdrawal of the vaccine in 2001. 44, 45 Although the pathogenesis of the vaccine’s effect on the seventh cranial nerve is uncertain, branches of the nerve do run near the nose. Other adverse neurologic effects of CT and LT have been hypothesized, based on their accumulation in the olfactory bulbs of BALB/c mice after nasal administration, sometimes with concurrent inflammation. 1063 As a result, recent adjuvant research has focused on subunits, detoxified versions, and other variants of CT and LT. 1064–1068 Several of these, such as CTA1-DD, do not accumulate in the olfactory bulb of BALB/c mice. 1062

Structural bacterial components

Other bacterial products that induce potent activation of the innate immune system include lipopolysaccharide and its derivative, monophosphoryl lipid A, as well as outer membrane proteins, flagellins, lipopeptides, filamentous hemagglutinins, and proteosomes. 1055, 1056–1059 The last are outer membrane proteins of meningococci, which self-assemble into hydrophobic, proteinaceous nanoparticles. 1060 An intranasally delivered, proteosome-based, inactivated influenza vaccine produced serum and mucosal antibodies in human subjects. 1064 N. meningitidis B proteoliposome-derived coelhate was demonstrated to be a potent mucosal adjuvant. 1060 Three doses of tetanus toxoid vaccine with this adjuvant administered by the IN route to mice promoted IgG serum titers and IgA titers in saliva and vaginal washes that were significantly higher than to tetanus toxoid alone.

Nucleotide stimulators of innate immunity

Oligodeoxynucleotides of cytosine and guanine with phosphodiester backbone (CpG ODNs) mimic motifs found in bacterial DNA. They are potent adjuvants, as the innate immune system recognizes these as pathogen-associated molecular patterns. 1069–1073 Abe and colleagues found that a nontypeable H. influenzae [NTHI] vaccine, delivered by the IN route with CpG ODNs, produced mucosal IgA and serum IgG responses similar to those produced by vaccine delivered with CT. Enhanced clearance of NTHI from the nasopharynx after challenge was shown equally in both groups. 1100 The inclusion of CpG ODNs with four HIV peptide antigens in microparticles delivered by the IN route to mice significantly enhanced peptide-specific IgG and IgA peak titers and prolonged the duration of these antibodies, and it increased the IgA response in mucosal washes. 1071 However, in another study, daily injections of high-dose [60 µg] CpG resulted in lymphoid follicle destruction and immunosuppression with liver necrosis after 20 days. 1072 Therefore, the potential adverse effects of CpG ODNs should be studied.

Protein signalers

Because many adjuvants induce the activation of cytokines and chemokines, investigators have looked at these cellular signaling molecules as adjuvants themselves that might reduce adjuvant toxicity. 1055–1059 Cytokines have been added directly to vaccine, or encoded for expression by a live vector or DNA vaccines. 1089 Bracci and colleagues found that, in mice, a single IN dose of an inactivated influenza vaccine provided full protection against virus challenge when the cytokine interferon type I was included as an adjuvant. 1090 Without it, the same dosage was only partially protective (40%). In mice, IN administration of pneumococcal surface protein A or tetanus toxoid, combined with the cytokine IL-1β, induced protective immunity equivalent to that induced by parenteral delivery. 1105

Natural polymers

Chitin is a natural polysaccharide found in crustaceans. Its partial deacytelylation yields chitosan, which is widely used in food products, as an excipient in drugs, and as a nutritional supplement. 1111 Chitin and chitosan have mucoadhesive properties and stimulate the innate immune system. 1112 In humans, the addition of chitosan to a detoxified diphtheria toxin based on CRM-197 significantly increased toxin-neutralizing antibody levels upon IN delivery. 1113 The saponins of the Quillaja saponaria tree are potent adjuvants with high toxicity. Quil A, QS-21, and Iscopen 703 are Q. saponaria derivatives with less toxicity. 1094 As an adjuvant for an IN HIV-1 DNA vaccine studied in mice, QS-21 consistently increased antigen-specific serum IgG and mucosal IgA compared with vaccine without adjuvant. 1114 Quil A and Iscopen 703 are commonly used as components of immunostimulating complexes.

Combining adjuvants for respiratory vaccination may synergistically enhance immune protection. For example, IN delivery to mice of an influenza recombinant hemagglutinin [HAI] antigen, along with a combination of proteosomes and lipopolysaccharide adjuvants, enhanced serum IgG and mucosal IgA antibodies up to 250-fold compared with vaccine alone. 1098 Also, IN delivery of an influenza vaccine with a combined CTA1-DD/ISCOM adjuvant vector was superior to other vaccine formulations using the ISCOM or CTA1-DD adjuvants alone. 1115

Nanoscale mixtures

Nanoemulsions are another class of adjuvants studied for respiratory vaccination. A soybean oil-in-water nanoemulsion was mixed with either US-licensed Fluzone, 97 or Fluvirin 443 inactivated, influenza vaccine [usually injected by the IM route], and delivered by the IN route to naïve ferrets. 1096 Resulting seroconversion rates were 67% to 100% against each of the three viral strains present in the vaccine. There was also protection against homologous
viral challenge and significant cross-immunity to five other H3N2 influenza virus strains not present in the vaccine.

Respiratory vaccination in veterinary practice

The respiratory route of vaccination is common in veterinary medicine. Aerosol vaccines for the IN route or by pulmonary inhalation are commercially available for cows (bovine herpes viruses 1, parainfluenza virus 3), pigs (Salmonella), horses (influenza, Streptococcus equi), dogs (Bordetella bronchiseptica), cats (feline calcivirus, feline herpesvirus 1), and chickens (infectious bronchitis virus, infectious laryngotracheitis virus, Newcastle disease virus). Almost all of the respiratory veterinary vaccines have live attenuated pathogens. In the United States, more than 8 billion chickens are vaccinated yearly using live attenuated vaccines delivered as aerosols or spray.

Respiratory vaccines for bioterror agents and pandemic threats

Many biological agents for potential bioterrorism or biowarfare cause life-threatening respiratory infections and would probably be disseminated as aerosols. Thus, vaccine-induced mucosal immunity may be advantageous. Compared with the parenteral injection, respiratory vaccination increased survival after aerosol exposures of deadly agents in animal studies. For example, a microsphere-based liquid anthrax vaccine delivered by the IN route to mice completely protected against aerosol challenge with anthrax spores. Two doses of human parainfluenza-virus-vectored Ebola vaccine were highly immunogenic in macaques and protected all animals against lethal Ebola virus challenge. A powdered formulation of anthrax vaccine with CpG ODNs administered intranasally to rabbits also provided full protection. Other bioterror agents for which respiratory vaccines have shown increased protection against aerosol challenge include Francisella tularensis (tularemia), staphylococcal enterotoxin B, Burkholderia mallei (glanders) and Y. pestis (plague).

The threatened pandemic of severe acute respiratory syndrome (SARS) in 2002-03, and the actual one of H1N1 influenza in 2009-10, illustrate the critical need for prompt development of new vaccines and their rapid delivery in all countries potentially affected. In responding to future threats when new vaccines may be required, respiratory delivery may be useful for the various reasons already described. Simple devices, such as single-use dry-powder inhalers, could be distributed by mail and self-administered for mass vaccination if congregating crowds for conventional campaigns were deemed unwise.

IN delivery of Salmonella-vectorized vaccine against the SARS coronavirus resulted in higher production of specific IgG and IgA than orogastric, intraportal, or intravenous administration, and it provided high levels of specific cytotoxic T lymphocytes in BALB/c mice. Two IN doses of live attenuated H5N1 influenza A vaccine fully protected mice and ferrets against pulmonary replication of homologous and heterologous strains of wild-type H5N1. Such cross-protection against diverse strains would be desirable for pandemic vaccine because of potential rapid changes in influenza surface antigens. For example, IN administration of inactivated, whole-virus H5N1 vaccine with adjuvant elicited immune responses with both sIgA in nasal, lung, and vaginal lavage, and IgG in serum, showing protective immunity against lethal H5N1 challenge and cross-clade protection. Also, aerosolized LAIV provided heterologous protection against pandemic H1N1 virus challenge in ferrets.

Conclusion

Cutaneous, jet-injected, and respiratory methods for vaccine delivery overcome the dangers and often the hidden costs of traditional needle and syringe. Some long-standing, many novel, these techniques may offer other advantages in terms of dosage sparing, immune response, economics, thermostability, patient and user preference, and expanded venues for use.

Many promising techniques described in this chapter, however, face daunting obstacles to bridge the gap between successful proofs of principle in animal models by academic laboratories, and the expensive and complicated series of clinical trials (particularly for the many target diseases lacking convenient laboratory assays that predict protection) and related studies and regulatory steps to achieve licensure. Indeed, the financing of all these stages requires investors to envision methods for their commercial-scale manufacturing and to predict demand in a rather monopsonistic market.

Finally, at the downstream outlet of the vaccine R&D pipeline, public health and immunization program policymakers, end-user purchasers, and (nowadays) independent philanthropic entities must be convinced by their own economic analyses and other considerations to pay for these fruits of immunization science. Perhaps some of the new technologies described and illustrated herein will help fulfill the widely admired goal that “all people deserve the chance to live healthy and productive lives.”
